## **Abstract**

We assess the relative impacts of receiving cash versus food transfers using a randomized design. Drawing on data collected in eastern Niger, we find that households randomized to receive a food basket experienced larger, positive impact on measures of food consumption and diet quality than those receiving the cash transfer. Other outcomes showed greater variation by season. Receiving food reduced the use of a number of coping strategies but this effect was more pronounced during the height of the lean season. Households receiving cash spent more money repairing their dwellings prior to the start of the rainy season and spent more on agricultural inputs during the growing season. Less than five percent of food was sold or exchanged for other goods. Food and cash were delivered with the same degree of frequency and timeliness but the food transfers cost 15 percent more to implement.

**JEL classification:** D04, I38, O12

## 1. Introduction

Interest in providing cash transfers for food assistance has been increasing in recent years. Cash transfers have known advantages relative to food transfers with respect to timeliness of delivery (Gentilini 2007; Lentz *et al* forthcoming). The other potential benefits and drawbacks of each form of transfer, across a range of criteria, depend on the context and objectives of the program (Upton and Lentz 2011). It is widely supposed that--as predicted by economic theory--recipients would prefer to receive cash; provided that cash transfers integrate the transaction costs involved in obtaining a comparable food transfer, recipients can better meet their diverse needs with a cash transfer. However, there is little *rigorous* evidence on the comparative impacts of cash and food transfers on food security and food related outcomes. There are numerous studies on the impact of cash transfers (see summaries in Fiszbein *et al* 2009 and DfID 2011) and numerous studies on the impact of food transfers (see Margolies and Hoddinott 2011). However, as Hidrobo *et al* (2012) note comparisons of these impacts is confounded by differences in program design, the magnitude of the transfer, and the frequency of the transfer.<sup>1</sup>

This paper contributes to our understanding of the impact of cash and food transfers on household food security. It uses a randomized design implemented by the World Food Programme (WFP) in the Zinder region of Niger. Niger is an appropriate venue for such a study. Following a famine in 2005, it has become a significant recipient of food assistance (WFP 2012). There are sharp seasonal dimensions to food insecurity in Niger and our evaluation design allows us to assess whether the impact of food and cash transfers varies by season.

We find that food and cash have different impacts on measures of food security. Households in villages randomized to receive the food basket experienced larger, positive impact on measures of food consumption and diet quality than those receiving the cash transfer. The likelihood of attaining an acceptable food consumption score was 10.9 percentage points higher for food households in July and 12.1 in percentage points higher in October. By contrast, households randomized to receive cash were more likely to make bulk purchases of grains. Other outcomes, however, showed greater variation by season. Receiving food reduced the use of a number of coping strategies but this effect was more

---

<sup>1</sup> See Hidrobo *et al* (2012) for a review of recent studies including work by Sharma (2006) and Cunha, De Giorgi, & Jayachandran (2011).

pronounced during the lean season. Households receiving cash spent more money repairing their dwellings prior to the start of the rainy season and spent more on agricultural inputs during the growing season. Less than five percent of food was sold or exchanged for other goods. Both food and cash were delivered with the same degree of frequency and timeliness but the food transfers cost 15 percent more to implement.

## **2. Contexts**

### ***Zinder region, Niger***

Niger is one of the poorest countries in the world. It is the fifth poorest when ranked by gross national income per capita (PPP dollars), 172 of 187 when ranked on life expectancy and 186 of 187 on the Human Development Index (UNDP 2012). Poverty in Niger is endemic; 65 percent of the population falls under the national poverty line of \$1.65 PPP per day, and the Human Development Report headcount index ranks nearly 93 percent of the population as suffering from deprivation (UNDP 2012). Only about 11 percent of Niger's land is considered arable, and crops suffer from volatility in rainfall and frequent drought. Even when food is available, there are systemic and periodic problems with access and use. Severe food crises affected parts of Niger in 2005-2006, 2010, and again in 2012.

The Zinder region is by Nigerian standards relatively well off.<sup>2</sup> It is in the southern part of the country that receives more rain than the arid north. Approximately 40 percent of Niger's millet production comes from Zinder and the nearby region of Maradi, and Zinder is a surplus production zone for millet and cowpeas, two key staples (FEWS 2010). Many inhabitants are agro-pastoralists, mixing agriculture with the raising of livestock primarily small ruminants. It is also a key commercial hub, in part due to its close proximity and close cultural ties to Nigeria (Eilerts 2006). Yet the region has frequently been among the hardest hit by food crises, and chronically suffers some of the highest rates of malnutrition (Grobler-Tanner 2006). During the 2005 famine, daily mortality rates were higher in Zinder than in any other region, and an estimated 65% of the population had to resort to 'irreversible' coping strategies such as selling large livestock or production tools (Reza *et al* 2008). These challenging conditions are embedded in a complex cultural landscape. Zinder is culturally dominated by the Hausa people, a traditionally agricultural people who speak the Hausa

---

<sup>2</sup> Outside of the capital, Niamey, Niger is divided into seven regions which in turn are divided into 36 *departements* which are further divided into *communes*.

language. They share Zinder with several smaller ethnic groups including the agro-pastoral Kanuri and the pastoral Peulh, Touareg, and Toubou.

### ***Experimental design***

In late 2010, the Government of Niger's (GoN) famine early warning system identified the Mirriah *departement* in Zinder as a place where humanitarian assistance would be required during the six month period before the September 2011 harvest. Given the availability of grains in local markets, WFP determined that it would be feasible to provide both food and cash to beneficiaries in this area.<sup>3</sup>

Within Mirrah, WFP in cooperation with the GoN identified 126 villages both in need of assistance and suitable for the public works envisaged as part of this intervention. Some villages were subsequently dropped because another organization was planning to provide food assistance to them or because the villages themselves declined to participate. Further investigation indicated that 13 villages had such poor market access that it was inappropriate to provide them with cash. These villages received transfers but were not included in the surveys leaving 79 villages that were both suitable for the project and that could receive either food or cash transfers. Implementing parties deemed that it would be too complicated and/or lead to tension if proximate villages—especially that shared a worksite during the public works phase—received different forms of transfer. Hence randomization was done at the worksite level. This led to 52 village or village cluster randomization units. Randomization was done through a procedure that assured an approximately equal distribution of villages/worksites by zone and size receiving each transfer.

The project was implemented in two phases over a six month period, from April through September 2011. Phase 1 involved public works activities that took place from April to June. Every household in participating villages was guaranteed 75 day's work on these projects.<sup>4</sup> Most worksites were located near the targeted villages. While participation in public works was voluntary, almost all households in these villages took part in work activities

---

<sup>3</sup> A market assessment in May 2011 confirmed that most traders in Zinder were still purchasing grain from local sources. Unlike the northern and western parts of Niger, Zinder is relatively secure which meant that heavily armed escorts would not be needed for cash disbursements.

<sup>4</sup> A small number of households such as those with a young mother and young children were exempted from the work requirement and given an unconditional payment.

(98 percent in the food transfer zone and 95 percent in the cash transfer zone). The registered beneficiary, who was usually the household head, was paid twice-monthly. In cash villages, they received 1000 FCFA (roughly 2 USD) per day worked to a maximum of 25000 FCFA per month. Food payments were provided in the form of a food basket of commodities similar to those typically eaten in the region. A day payment provided a full ration of food for the average household size of seven people, including 3.5 kg of grain (primarily maize in the first transfer period and sorghum in the second), 0.72 kg of pulses (cowpeas, red beans, or lentils), 0.14 kg of vegetable oil, and 0.035 kg of salt. Based on the average monthly prices of these commodities between April and September 2010, the average monthly cost of this food basket to recipients was 24000 FCFA. During the design phase, respondents told project staff that it would cost approximately 800 FCFA to make four trips per month to markets to buy food. Subtracting these transport costs made the value of the food basket and the cash transfer equivalent.<sup>5</sup> The transport, storage and distribution of food and cash payments were contracted out to several Nigerian non-governmental organizations. For the cash transfers, they charged WFP a fixed percentage of the total amount of cash distributed. For food transfers, they charged a monetary fee based on the quantity of food delivered. These transport, storage and distribution costs were 15.4 per cent higher for food relative to the cash payments.<sup>6</sup>

During the second phase, from July through September, 50 percent of households in each village were selected to continue to receive the same transfer without having to fulfill a work requirement; this was dropped out of concern that public works activities would interfere with the planting and weeding of crops during the agricultural season. Targeting of unconditional transfer recipients was undertaken using a combination of demographic

---

<sup>5</sup> Respondents at the community level indicated that on average it cost 480 FCFA (roughly 1 USD) to transport 100kg of cereals from the market to home, or otherwise 1920 FCFA for the transfer period (four trips). This figure, however, does not take into account households pooling transport costs, which could significantly reduce the per-household cost. The average cost for obtaining the food transfers by beneficiaries was reported to be only 60 CFA per trip.

<sup>6</sup> These calculations abstract from a number of fixed costs associated with setting up these payments. For example each smart card used for the cash payments cost \$6.00 and there were additional costs associated with writing the computer programs needed to dispense payments through the mobile ATMs. Costs such as these are not included in the calculations reported here. We exclude costs that were common to both the food and cash payments such as costs associated with implementing the public works, identifying the beneficiaries, program sensitization, identification of implementing partners and contract negotiations with MFIs selected to implement this intervention.

targeting and a participatory approach.<sup>7</sup> A locality selected to receive cash(food) used cash(food) for both public works and unconditional transfer payments.

### **3. Data**

The first survey was implemented in July, at the conclusion of the public works but before the roll-out of the unconditional transfer.<sup>8</sup> All households in all villages were administered a basic questionnaire. A randomly selected sample of 2268 households who had been targeted for the unconditional transfers was interviewed in greater depth. A follow up survey was then administered to the sampled households at the conclusion of the unconditional transfers, with 2209 being successfully traced and interviewed, an attrition rate of 2.6 percent.

In both rounds household and community surveys were administered. The household survey instruments included questions on demographic characteristics, livelihoods, assets, livestock, agricultural production, and public works participation. Pre-intervention characteristics (ie as of April 2011) including household composition, asset ownership and indebtedness were retrospectively assessed as part of July survey. Food security impacts and intra-household sharing were captured in modules on food consumption, coping strategies and children's food consumption. The survey instrument also included questions on non-food expenditures, debt, inter-household transfers, migration, and labor force participation. The community survey instrument collected information on access to services, proximity and distance of markets, prices on key staples and livestock, and criteria for selection of beneficiaries for the unconditional transfers.

Table 1 provides pre-intervention descriptive statistics of households using information found in the retrospective components of the survey instrument.<sup>9</sup> These data are reported as worksite means, disaggregated by whether the locality was randomized to

---

<sup>7</sup> The implementing agencies made the selection in partnership with village leadership committees, with reference to a set of categorical indicators such as households with children under the age of 24 months, single parent household, etc.

<sup>8</sup> Impact evaluations usually have baseline surveys prior to the start of the intervention, though as McKenzie (2012) notes, this is not always necessary. In our case, several factors prevented us from doing so. The security situation in Niger at the start of 2012 was poor and this severely limited access by the research team to the study sites. There was considerable uncertainty regarding take-up if public works and the targeting of unconditional recipients had not been fully completed prior to first payments being made in April 2012.

<sup>9</sup> We provide unweighted statistics. Using sampling weights that reflect the inclusion probability of the households in the sample have a minor impact on the results.

receive food or cash. Households are relatively large. About third are either polygamous or female headed. They are poor. Fewer than 10 percent of heads have any formal schooling.<sup>10</sup> While nearly all households own or rent farmland, and average operating sizes look large, this is land of very low quality. Housing quality is poor and the vast majority of households own little in the way of productive assets or consumer durables. We summarize these in the form of an asset index. Around 30 per cent of households report that they own no livestock and another 12 percent own only chickens or one ruminant. We convert data on livestock holdings to Tropical Livestock Units (TLU). Households own, on average, one TLU. There are no statistically significant differences across treatment arms when we look at a wide range of household demographic, asset, or livelihood characteristics.

Table 1 also provides information on locality characteristics aggregated at the worksite level. About two-thirds of villages are accessible by road. It typically takes just under one hour to reach a road and about the same time to access a market. There are relatively few food markets in these villages. Nearly all have cell phone coverage. There are no statistically significant differences across treatment arms in infrastructure.

The survey module on household food security identified which foods were consumed and the frequency of their consumption over the previous seven days. The specific items selected were based on previous survey work in this area as well as discussions with key informants. While the survey instrument did not collect information on quantities consumed, it distinguished between foods that are served as a separate item and foods that are used only as a sauce or condiment. We use these data to construct two measures of household food security: the Dietary Diversity Index (DDI) and the Food Consumption Score (FCS). DDI is calculated by simply summing the number of distinct food categories consumed by the household in the previous seven days. The household questionnaire covers 25 such food categories, and thus the DDI in this survey ranges from 0 to 25. Hoddinott and Yohannes (2002) show that the DDI correlates well with both household dietary quantity and quality. Next, we aggregate these 25 food categories into eight groups: staples, pulses, vegetables, fruit, meat/fish, milk/dairies, sugar/honey, oils/fats. The FCS is calculated by summing the number of days each food group was

---

<sup>10</sup> Formal education refers to the completion of at least one year of primary schooling. We exclude attendance at Koranic schools because individuals attending these do not necessarily learn to read and write.

consumed then multiplying those frequencies by a predetermined set of weights designed to reflect the heterogeneous dietary quality of each food group (Weismann *et al* 2009).<sup>11</sup>

Three considerations motivate our use of these outcome variables. First, the FCS is considered a “core” indicator by WFP (WFP 2008) and the success of interventions such as the one evaluated here is measured by improvements in this outcome. Second, validation studies show that the FCS is highly correlated with measures of food security that draw on more detailed food consumption data such as per capita caloric availability derived from seven day recall of food quantities consumed (Wiesmann *et al* 2009). Third, logistical constraints meant that we needed to keep the survey instrument as simple as possible. It was simply impractical to include a more detailed consumption module.

Table 2 describes these outcomes variables by both round and modality. The DDI shows us that in July 2011 households consumed on average 8.2 foods out of the list of 25 items, and in October (following the 2011 harvest) on average 9.2. When we compare individual food groups over time, we see increases of five to 15 percentage points in the proportion of households consuming vegetables, oils, pulses, dairy, sugars, tubers and meats. There is no meaningful change in the proportion of households consuming fruit, fish or eggs.

WFP classifies households as having poor food security when the FCS falls below 21, borderline when it lies between 21 and 35, and acceptable if over 35. Loosely, a cut-off of 35 corresponds to daily per capita caloric availability of around 1950 kcal. Food insecurity is widespread in this sample in July 2011; while the full sample average is 40.8, 33 percent of households have borderline food insecurity and 24.7 percent have poor food insecurity. These figures improve significantly in October, with the full sample average FCS up to 47.3, those with borderline down four percentage points to 29 per cent and those with poor down to only 9 per cent. Figure 1 shows the density of FCS by transfer modality in July and October, with the rightward shifts in October indicating improvement for both cash and food households. Table 1 shows that households in localities that were randomized to receive food have higher mean levels of DDI and FCS.

We also consider a second measure of food security, household coping strategies. These actions taken by individuals or households who, under stress, restrict expenditures or

---

<sup>11</sup> Weights are: staples, 2; pulses, 3; vegetables, 1; fruit, 1; meat, poultry, fish and eggs, 4; dairy 4; sugars, 0.5; oils and fats, 0.5

generate additional resources so as to acquire basic consumption goods (food, shelter) while protecting existing asset holdings. As Devereux and others have stressed (e.g. Devereux, 1993), these exist along a continuum from those that involve relatively modest shifts in consumption patterns to more extreme behaviors such as going without food for a full day. The household survey instrument contained a set of questions on household coping strategies. We look in turn at a range of food-related coping strategies, such as not having to borrow or beg for the means to purchase food, consuming undesirable foods, or reducing portion sizes or the number of meals. We then construct a Coping Strategies Index (CSI) following Maxwell and Caldwell (2008), as an aggregate measure of food security. Each strategy is given a frequency score depending on the number of times it was used and a weight reflecting its severity. There is significant improvement in the coping strategies index over the course of the second round of intervention between July and October, from an average of 5.4 to an average of only 0.8. There are significant differences in both periods between cash and food households, but this gap closes between July and October.

We hypothesized that beneficiaries might use their transfers to buy food in bulk. Since the notion of a “bulk” purchase is somewhat subjective, in both survey rounds we asked this in an open ended fashion. For example, in the July survey this was phrased as *“Depuis avril 2011, avez-vous acheté des graines en plus grande quantité que vos achats de grains habituels?”* (“Since April 2011, have you purchased grains in larger quantities than you usually purchase?”) In July, 504 out of 2,263 households (22.2 percent) indicated that they had made such a purchase, 85 percent of whom were households in villages randomly assigned to receive cash. We then asked the cash value of such purchases. We also examined non-food expenditures across a range of categories. There are some differences between cash and food households, as well as between periods, but most are small in magnitude (Table 3). Cash households spend more for example on wages, veterinary products, and seeds, in both July and October, while food households spend somewhat more on a few other items. Cash households do however spend significantly more on average on bulk grains; they are nearly 30 percentage points more likely to invest in ‘larger quantities of grain than usual,’ and spend larger sums, in both periods.

#### **4. Methods**

We begin with a single difference model of the form

$$y_{iw} = \alpha + \delta food\ village_i + \varepsilon_{iw} \quad (1)$$

where  $y_{iw}$  is the outcome of interest for household  $i$  at worksite  $w$  after the intervention and  $food\ village_i$  is a dummy variable equal to one if a household lives in a village receiving food (and 0 otherwise). The parameter  $\delta$  is the parameter of primary interest. It tells us the impact on outcomes of being randomized into a village receiving food relative to being randomized into a village receiving cash. We allow for the error terms to be correlated by clustering at the worksite (randomization) level. The randomization of the modality ensures that  $E(food\ village_i \varepsilon_{iw})$  equals 0 and thus that  $\delta$  is an unbiased estimate of impact.

Because we do not observe pre-intervention food security outcomes, we cannot estimate a double difference model. McKenzie (2012) argues that difference-in-difference estimators are preferable to a post-intervention estimator only when the autocorrelation of the outcome variables is relatively high. He notes that this will not be the case for outcomes such as consumption that fluctuate over time. Further, he notes that conditioning on variables that are correlated with the dependent variable can reduce the variance of the treatment estimator. Accordingly, we estimate the following model

$$y_{iw} = \alpha + \beta X_i + \delta food\ village_i + \varepsilon_{iw} \quad (2)$$

where  $X_i$  is a vector of household baseline covariates and village characteristics. These include household demographics such as size and head characteristics such as sex, age and level of education. We control for ethnicity and for ownership of durables which acts as a proxy for household wealth. We control for livelihood zone (agricultural, agro-pastoral), whether or not there is a market and a cereal bank in the village, the price of millet at the end of the transfer period and the change in the price of millet over the transfer period. We also control for cattle prices (milk cows and a goats) as reported in our community surveys. We control for the distance to a main highway and whether or not the village has mobile network coverage and for commune fixed effects.<sup>12</sup> We estimate (2) separately for outcomes measured in July and in October. We use OLS for outcomes that are continuous,

---

<sup>12</sup> For brevity, we only report  $\delta$  in our tables. Full results are available on request.

probits where they are dichotomous, Poisson regressions where we have count data and tobits where the outcome is continuous but also censored at zero. Estimates of  $\delta$  are transformed into marginal effects where the estimator is non-linear. Standard errors are calculated accounting for clustering at the unit of randomization.

## 5. Results

### *a. Food security*

Table 4 shows the impact of residing in a village whose worksite was randomized to receive food transfers on the DDI, FCS and whether the FCS was above the WFP cut-off for a minimally acceptable diet.

We begin with the DDI. There is a small, positive impact of being in a village receiving food on the DDI, an additional 0.36 food items in July and 0.54 items in October. But these magnitudes are relatively small, corresponding to increases of 4.9 and 6.7 percent respectively. By contrast, there are large, positive and statistically significant impacts of the receipt of food on the FCS. After controlling for household and village characteristics, households in localities receiving food have an FCS on average 3.9 points higher than cash households in July and 4.6 points higher in October, relative to an over-all mean FCS in July of 40.8. The likelihood of having an acceptable food consumption score is 10.9 percentage points higher for food households in July and 12.1 percentage points higher in October.

Table 5 reports the impact of access to food transfers on the likelihood and frequency of consumption of selected food groups in the seven days prior to the survey. We find that relative to households receiving cash, households in villages randomly assigned to receive food consumed more of the items given to them in the food basket: cereals, pulses and oil. They also increased the frequency of their consumption of these items: increasing their consumption of oils by one day and pulses by 0.6 days. By contrast, their consumption of cheap, starchy calories from tubers declines. There is no differential effect on the frequency of consumption of meat, dairy, fruit or vegetables. This is consistent with information food recipients provided to us. Only 5 percent of food recipients reported that they sold some of the food, and 13 percent that they exchanged some of the payment for other food or non-food items. Just 1.2 percent of all food received was sold and only 3.7 percent exchanged.

Table 6 shows the results of estimating our single difference equations for the July and October survey rounds where the dependent variables are the likelihood of making a large grain purchase and the value of this purchase. In the three months prior to the July(October) survey, households in food localities were 27(40) percentage points less likely to make these purchases relative to households in cash localities. The marginal impact was a reduction in the value of such purchases of 14,289 FCFA in July and 25,015 FCFA in October. In other words, it appears that relative to households in food localities, households receiving cash used a significant proportion of their transfers to purchase the cheapest form of calories available.

One reason lies in the sharply seasonal nature of grain prices in this region. Agriculture production is characterized by volatile conditions and one fairly short growing season. The climate is hot and dry year round, but hottest in May, right before the brief but at times intense rainy season of June to August. Field preparation may start as early as April but peaks between July and September, the pre-harvest period known as the *soudure* or hungry season. Millet, the dominant food produced and consumed throughout Niger, is surplus in production throughout much of the southern part of the country, especially Zinder, where millet is sourced for much of the country. Niger often produces a deficit, however, and imports millet from Nigeria, Benin, and Burkina Faso during the hungry season. The seasonality of production patterns and trade flows leads to inter-seasonal fluctuations in the prices of key staple commodities in Zinder.

This seasonality, as is shown in Figures 2a and 2b, provides clues as to why we may be observing these bulk purchases of grains by households in cash villages. Figure 2a shows that historically grain prices in the survey area, both millet and maize, rise between January and August. They fall sharply during the harvest period before starting to rise again in November. Figure 2a also shows that this pattern was somewhat different in the year prior to the intervention. Not only were grain prices significantly above historical averages, millet prices rose faster than the historical average. Figure 2b shows that in the four months prior to the start of the intervention, both millet and maize prices were again rising, with April 2011 prices already equal to or higher than the highest price typically observed during the peak of the hungry season. Given this historical experience, it is understandable that cash households may have felt compelled to buy large grain quantities rather than risk exposure to uncertain food price changes.

### ***b. Coping strategies and non-food expenditures***

Table 7 examines the coping strategy index (CSI) and individual coping strategies used by households to acquire food. Recall that the higher the CSI, the more severe the coping strategies used. Households in food localities have a lower CSI than cash households in July and October. In July, food households were less likely to report that they consumed less preferred foods, were less likely to report that they reduce portion sizes served to children or that household members went to be hungry. While the marginal effects look small, they are relatively large compared to the mean values reported in Table 3. However, these effects on more severe coping strategies are less marked in October as the harvest period begins.

We considered whether households in food and cash villages had different patterns of expenditures on non-food items (Table 8). Across all items, the marginal impact of being in a food village is to raise monthly expenditures on all non-food items by 1874 FCFA in July. This is equivalent to about eight percent of the value of the monthly transfer. There is no statistically significant impact on all non-food items in October. Across the individual items, it is difficult to discern consistent patterns. Only eight of the 18 coefficients are statistically significant at the 10 percent level or higher and the magnitude of two of these (firewood and other fuels; soap, perfumes and hair products) is small, less than 500 FCFA. The most noteworthy finding is that households in cash villages spent more on agricultural inputs in both the lead up and during the main cropping season and the magnitude of this effect especially in October (5819 FCFA or just over 20 percent of the monthly transfer) was large. Also, households in cash villages spent some of their transfers on repairing their dwellings in the three months prior to the July survey, in advance of the rains.

### ***c. Additional results***

We considered whether there were larger changes over time in households residing in localities assigned to receive food. To do so, we also estimated models of the following form:

$$y_{iwOctober} - y_{iwJuly} = \alpha + \beta X_i + \delta food\ village_i + \varepsilon_{iw} \quad (3)$$

Generally, across the outcomes we consider,  $\delta$  is not statistically significant when we estimate (3), that is, we do not reject the null hypothesis that changes in outcomes over time are different in food and cash villages. The exception to this are the results for specific coping strategies where  $\delta$  is negative and significant for a number of the more severe coping strategies such as reducing children's portion sizes and going a whole day without eating.

We looked for evidence of heterogeneous impacts along two dimensions, household wealth and the gender of the household head. Across all outcomes we consider and across both survey rounds, we do not find any evidence that the interaction terms between gender of head and residing in a village receiving food are statistically significant. Across all outcomes measured in the July round, the interaction terms between wealth (measured in tertiles, quartiles or quintiles) and residing in a village receiving food are not statistically significant. In the October round, households in the lowest quartile and in food villages obtained greater improvements in the FCS measure and were less likely to have poor food security status. Overall, however, we found little evidence of heterogeneous impacts across wealth categories and gender of head.

## **6. Conclusions**

In this paper, we have used a randomized design to inform debates regarding the use of cash and in-kind transfers as a means of improving household food security. With respect to the short term food security objectives of this intervention, the food basket had clear advantages. Households in localities randomized to receive the food basket experienced larger, positive impacts on measures of food security and dietary diversity than those receiving the cash transfer. One reason that the cash recipients had less diverse diets lies in their choice of purchasing grains in bulk, a reflection we perceive of both the extreme poverty found in this area and uncertainty regarding future food prices. While these differences held in both periods, other outcomes showed greater variation by season. Households receiving food resorted to fewer coping strategies, and this effect was more pronounced during the height of the lean season than during the growing season. Food recipients did not trade their transfers to any large extent; less than five percent of food was sold or exchanged for other goods. Households receiving cash spent more money repairing their dwellings during the lean season, prior to the start of the rains, but spent more on

agricultural inputs during the growing season. Both food and cash were delivered with the same degree of frequency and timeliness, but the food transfers cost 15 percent more to implement.

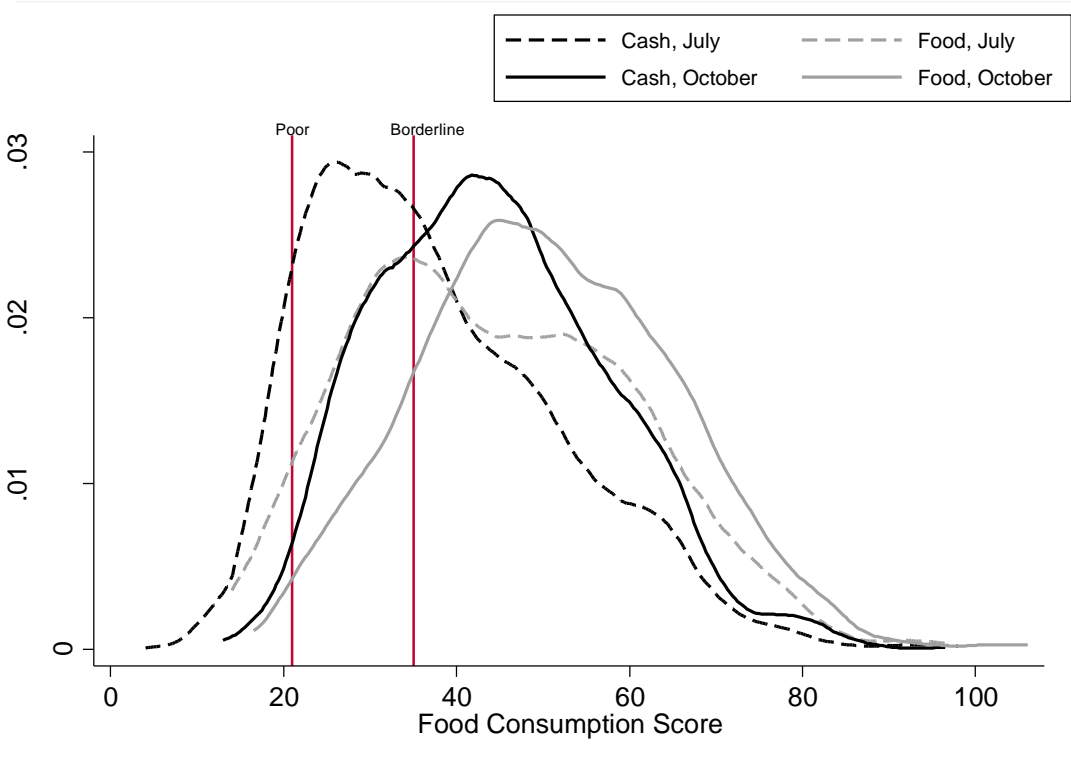

While food recipients experienced greater food security benefits in the short term, we cannot assess the relative benefits in the long term; the fact that beneficiaries receiving cash spent more on agricultural inputs may mean that these households have higher incomes in the future. Finally, the specific context of this study is important. Our results are informative about the relative impacts of food and cash transfers in an extremely poor, rural setting, but caution should be exercised in extrapolating them to settings much different than those found in rural Niger.
