The Production Theory Approach to Import Demand Analysis: A Comparison of the Rotterdam Model and the Differential Production Approach

Andrew A. Washington and Richard L. Kilmer

Results indicate that, when comparing the unconditional derived-demand elasticities to the unconditional consumer demand elasticities, significant differences emerge due to the differences in the first-stage estimation procedure between the differential production approach and the Rotterdam model. In comparing the consumer demand price/cross-price elasticities to the derived-demand price/cross-price elasticities, it is clear that use of the Rotterdam model when a production approach should be used can lead to overestimation, underestimation, and incorrect signs in deriving unconditional price effects.

Key Words: dairy, demand, imports, international, production, Rotterdam, trade

JEL Classifications: D12, D24, F10, F14, Q17

The Rotterdam model application to import demand has been accomplished by a number of studies (Lee, Seale, and Jierwiriyapant; Seale, Sparks, and Buxton; Zhang, Fletcher, and Carley). In past studies, imports are considered to be final goods that enter directly into the consumer’s utility function and the resulting demand equations for imports are derived from utility maximization theory. However, given the nature of international trade, where traded goods are either used in other production processes or go through a number of domestic channels before reaching the consumer, it is more appropriate to view imported goods as intermediate products than as final consumption goods even if no transformation takes place (Davis and Jensen). The primary objective of this article is to compare and contrast the use of the differential production approach with the Rotterdam model. Both approaches are applied to Japan’s derived demand for imported whey differentiated by source country of production. Unconditional elasticities from both approaches are then compared.

The application of production theory to international trade is by no means a new concept. Past research that used a production theory approach to international trade include Burgess (1974a,b), Kohli (1978, 1991), Diewer and Morrison, and Truett and Truett. Each of these studies acknowledged that most goods entering into international trade require further processing before final demand delivery. They further acknowledged that, even when a traded...
product is not physically altered, activities such as handling, insurance, transportation, storing, repackaging, and retailing still occur. This results in a significant amount of domestic value added when the final product reaches the consumer. Therefore, it is more appropriate to view imported products as inputs rather than as final goods even if goods are not transformed.

Davis and Jensen (pp. 410–12) meticulously discuss the advantages of the production theory approach over the utility approach to import demand estimation. Their first point is that most imported agricultural commodities are inputs and not final goods. Second, specifying the first-stage aggregates is more intuitive when using the production theory approach. Third, it is easier and more intuitive to estimate unconditional elasticities using production theory. Their last point is that the estimated parameters using production theory will be structural parameters.¹

Kohli (1991) notes that viewing imports as intermediate goods not only has its merits in correctness but it also leads to substantial simplifications theoretically. One simplification is that the demand for imports can be derived from production theory and there is no need to model final demand. Second, this approach allows for the avoidance of the difficulties that arise when we aggregate over individual consumers. To expound on this point, data is typically reported in aggregate terms. Therefore, if we are estimating demand, we are estimating aggregate demand, and if we are estimating derived demand, it is aggregate or industry derived demand. The differences between aggregate demand and aggregate derived demand is that one is an aggregation over consumers and the latter is an aggregation over firms. When we consider optimizing behavior by both consumers and firms, do the properties derived from consumer and producer-maximizing behavior hold in the aggregate? Mas-Colell, Whinston, and Green indicate that, when consumer preferences and wealth effects are identical across consumers, the aggregate demand function satisfies all of the properties of an individual demand function.² However, if there is the slightest difference in preferences and if these differences are independent across consumers (as one would expect), the property of symmetry, which is a common property tested in most empirical demand studies, will almost certainly not hold.³

When we aggregate across firms, there are no such conditions required for the properties of optimal firm behavior to hold in aggregation. This is because the aggregate profit obtained when each production unit maximizing profit separately, taking prices as given, is the same as that that would be obtained if they were to coordinate their actions in a joint profit-maximizing decision (Mas-Colell, Whinston, and Green).⁴ This result implies that the profit-maximizing output arrived at if all firms coordinated their actions is the same as the sum of the individual output of each profit-maximizing firm. It further implies that the total cost of production for the coordinated output is the same as the sum of total cost for each individual firm if firms are price takers in the input market (Mas-Colell, Whinston, and Green). Therefore, if we estimate input demand functions and output supply functions using aggregate data, the properties of the demand and supply functions for each individual firm will theoretically hold in aggregation.⁵

¹ The properties of a system of demand equations for a utility maximizing consumer are adding up, homogeneity, and the symmetry and negative semidefiniteness of the matrix of price effects.
² The property of negative semidefiniteness holds in aggregation under less strict conditions. If each individual demand function satisfies the uncompensated law of demand, then the aggregate demand function satisfies the weak axiom of revealed preference, which implies a negative semidefinite price effect matrix.
³ Prices are assumed as given even with coordination.
⁴ The properties of the input demand function are the same as the properties of the consumer demand function. The property of the supply function is that the matrix of price effects is symmetric and positive semidefinite. The authors assumed that firms are still price takers even with coordination. Production technology can vary over firms.

¹ For a more in-depth discussion of the conceptual and theoretical advantages of the production approach, see Davis and Jensen.
Overview of Theory

The differential approach to the theory of the firm is comparable with the differential approach to consumer theory proposed by Bar-ten (1964) and Theil (1965). The empirical application of the differential approach to consumer demand resulted in the Rotterdam model, which has been used extensively in demand studies and to a lesser extent in import demand studies. The majority of import demand studies that used the Rotterdam model assumed that imported goods entered directly into the consumer’s utility function and strong assumptions were made about how consumers view imported and domestic goods and how they grouped commodities. Furthermore, it was often assumed that these commodity groups were to some degree independent in terms of the consumer’s utility function (e.g., see Lee, Seale, and Jierwiriyapant; Seale, Sparks, and Buxton; and Zhang, Fletcher, and Carley). In these studies, the intermediate nature of imports was not considered.

The Rotterdam Model

The estimation of import demand using the Rotterdam model is accomplished in two stages. First, consumers allocate total expenditures between product groups (first stage) and, second, consumers allocate total group expenditures among goods within the product group (second stage). It is also assumed that product groups are blockwise dependent, i.e., the utility interactions among goods are a matter of the groups and not the individual goods.

The first stage of the consumer budgeting process results in a system of composite demand equations, where each equation is expressed as

\[ W_i d(\log Q_i) = \Theta_i d(\log Q) + \sum_{k=1}^{G} \Pi_{ik} d(\log P'_k), \]

where \( d(\log Q_i) \) and \( d(\log P'_k) \) are the group Divisia volume and Frisch price indexes, respectively; \( W_i, \Theta_i, \) and \( \Pi_{ik} \) are the budget share, marginal share, and absolute price coefficient, respectively; and \( d(\log Q) \) is the percentage change in real income (Theil, 1980, p. 101). Equation (1) states that the composite demand for the product group depends on real income and the Frisch price indexes for each group. The size of the system represented by equation (1) is equal to the total number of groups specified in the consumer’s utility function. When estimating import demand, the total number of equations in the system can be as large as the total number of goods imported, which makes estimating equation (1) problematic.

The demand for individual goods within a group conditional on total group expenditures (second stage) results in a system of demand equations where each equation is expressed as

\[ w_i d(\log q_i) = \theta_i d(\log Q_i) + \sum_{j=1}^{n} \pi_{ij} d(\log p_j), \]

where \( w_i \) represents the share of group expenditures allocated to good \( i \) and \( \theta_i \) is the conditional marginal share; \( q_i \) and \( p_j \) are the quantities and prices, respectively; \( \pi_{ij} \)'s are the conditional Slutsky price coefficients; and \( n \) is the number of goods within the product group (Theil, 1980, p. 103).

Dividing equation (1) by \( W_i \) and substituting into equation (2) yields the unconditional demand equation

\[ w_i d(\log q_i) = \frac{\Theta_i}{W_i} d(\log Q) + \sum_{k=1}^{G} \frac{\Pi_{ik}}{W_i} d(\log P'_k) + \sum_{j=1}^{n} \pi_{ij} d(\log p_j). \]

From equation (3), we get the unconditional income elasticity

\[ \frac{\partial q_i}{\partial Q} = \frac{\Theta_i}{W_i} + \sum_{k=1}^{G} \frac{\Pi_{ik}}{W_i} \left( \frac{\partial P'_k}{\partial Q} \right) + \sum_{j=1}^{n} \pi_{ij} \left( \frac{\partial p_j}{\partial Q} \right). \]

\[ \frac{\partial q_i}{\partial Q} = \frac{\Theta_i}{W_i} + \sum_{k=1}^{G} \frac{\Pi_{ik}}{W_i} \left( \frac{\partial P'_k}{\partial Q} \right) + \sum_{j=1}^{n} \pi_{ij} \left( \frac{\partial p_j}{\partial Q} \right). \]
\[
\eta_i = \frac{d(\log q_i)}{d(\log Q)} = \frac{\theta_i \Theta_s}{w_i W_g},
\]
which is the product of the conditional expenditure elasticity \(\theta_i/w_i\) and the expenditure elasticity for the group \(\Theta_s/W_g\). We also get the unconditional price elasticity
\[
\eta_u = \frac{d(\log q_i)}{d(\log p)} = \frac{\theta_i \Pi_{eb}/W_s}{w_i W_g} + \pi_{ij}/w_i,
\]
where \(\Pi_{eb}/W_g\) is the own-price elasticity for the group \(\pi_{ij}/w_i\) is the conditional price elasticity for the \(i\)th good.

The Differential Production Approach

Using the methodology of Laitinen and Theil, Laitinen, and Theil (1980), the differential production model will also be used to estimate the import demand. The differential production model is derived from the differential approach to the theory of the firm where firms maximize profit in a two-stage procedure. In the first stage, firms determine the profit-maximizing level of output to produce, and in the second stage, firms minimize the cost of producing the profit-maximizing level of output. According to Laitinen and Theil and to Davis and Jensen, this procedure is consistent with a one-step or direct profit-maximization procedure. In the first stage, the output supply equation is obtained, and the conditional factor demand system is obtained in the second stage. Using the results of both stages, a system of unconditional derived-demand equations is derived.

In the first stage, a competitive firm seeks to identify the profit-maximizing level of output by equating marginal cost with marginal revenue. This procedure yields the differential output supply equation
\[
d(\log Q^*) = \varphi d(\log p^*) + \sum_{j=1}^{n} \pi_j d(\log w_j),
\]
where \(Q^*, p^*,\) and \(w_j\) represent the output, output price, and the price of inputs, respectively, and \(\varphi\) and \(\pi\) are the price elasticity of supply and the elasticity of supply with respect to input prices, respectively. \(N\) is the total number of inputs used in production.

In the second stage, the differential factor demand model is derived, which will be used to estimate the system of source-specific derived-demand equations. This model is specified as
\[
f_i d(\log x_i) = 0, \quad d(\log X) + \sum_{j=1}^{n} \pi_{ij} d(\log w_i),
\]
where \(f_i\) is the factor share of imported good \(x\) from source country \(i\) in total input cost; \(x_i\) and \(w_i\) represent the quantity and price of inputs that include the price of each imported good from source country \(i\);
\[
d(\log X) = \sum_{i=1}^{n} f_i d(\log x_i),
\]
where \(d(\log X)\) is the Divisia volume input index; \(\theta_i^*\) is the mean share of the \(i\)th input in the marginal cost of the firm; \(\pi_{ij}^*\) is the conditional price coefficient between the \(i\)th and \(j\)th importing sources or inputs; and \(n\) is the number of inputs in the system, \(n \in N\).

The differential factor demand model requires that the following parameter restrictions be met in order for the model to conform to theoretical considerations
\[
\sum_{i} \pi_{ij}^* = 0 \quad \text{(homogeneity)}
\]
and \(\pi_{jj}^* = \pi_{jj}^* \quad \text{(symmetry)}\). The second-stage procedure results in the conditional own-price/cross-price elasticity
\[
e_{ix} = \frac{d(\log x_i)}{d(\log w_j)} = \frac{\pi_{ij}^*}{f_i},
\]
and the conditional Divisia volume input elasticity,
\[
e_{ix} = \frac{d(\log x_i)}{d(\log X)} = \frac{\theta_i^*}{f_i}.
\]

Using the relationship between the Divisia volume input index and output, \(d(\log X) = \ldots\)

\(^7\) The derivation of equations (6) and (7) are found in Laitinen and Theil.
\( \gamma d(\log Q^*) \), equation (6) can be substituted into equation (7) to yield the unconditional derived-demand system

\[
(10) \quad f_i d(\log x_i) = \theta_i + \gamma d(\log p^*) + \sum_{j=1}^{n} \pi_j d(\log w_j)
\]

Dividing through equation (10) by \( f_i \) and using equations (8) and (9), we get the unconditional derived-demand elasticities. The unconditional elasticity of input demand with respect to output price is

\[
(11) \quad \varepsilon_{op} = \frac{d(\log x_i)}{d(\log p^*)} = \gamma e_{xy}\Psi,
\]

And the unconditional own-price/cross-price elasticity of input demand is

\[
(12) \quad \varepsilon_{xx} = \frac{d(\log x_i)}{d(\log w_j)} = \gamma e_{xy}\pi_j + \varepsilon_{xw}.
\]

Last, we get the unconditional elasticity of derived demand with respect to the price of an input contained in \( N \) but not in \( n \):

\[
(13) \quad \varepsilon_{uw} = \frac{d(\log x_i)}{d(\log w_j)} = \gamma e_{xy}\pi_j.
\]

Inputs contained in \( N \) but not in \( n \) include labor and other inputs that are not part of the imported whey group.

The second-stage procedures in the consumer and production approaches yield empirically identical demand systems, equation (2) and equation (7), resulting in identical conditional elasticities. Davis and Jensen note that this similarity explains the empirical success of consumer-based conditional demand systems even though they may be conceptually flawed. However, given the differences in the first stage, equation (1) and equation (6), unconditional elasticities differ between the two approaches. Also, the production approach results in the unconditional elasticity of derived demand with respect to output price whereas the Rotterdam model results in the unconditional income elasticity. This suggests that the use of the Rotterdam model, when a production approach is more appropriate, not only leads to biased unconditional own-price/cross-price elasticity estimates but also leads to the reporting of unconditional income elasticities when the concern should be the unconditional elasticity of derived demand with respect to output price.

**Application to the Derived Demand for Imported Whey in Japan**

This study assesses the competitiveness of whey imports into Japan from the United States compared with whey imported from other countries such as the European Union (E.U.), Australia, and New Zealand. Following Armington, similar imported dairy products such as E.U. whey and U.S. whey are both individual goods that are part of the product group whey but they are different based on their source country of production. There are a number of reasons why similar products are viewed as different based on their source country of origin. Dairy products from different sources may actually be physically different. Physical differences include quality, protein, fat content, and taste. There may also be perceived differences, such as a country’s reputation for a quality product, trade history, reliability, and consistency, and political issues tied to trade (Zhou and Novakovic). The crux of this assumption is that within an importing country, a particular dairy product imported from a given source is considered a substitute for that same product from another source. However, because of the physical and perceived differences attributed to the product due to its origin, these products are imperfect substitutes.

In this article, it is assumed that dairy prod-
ucts are imported through firms that exclusively import. Although there are firms within Japan that import whey as well as transform whey into other products, it is assumed that there is a separate entity within the firm that deals primarily with the procurement of imported dairy products. Also, dairy imports through this type of firm make up a smaller percentage of imports in Japan. In addition to providing imported products to other firms, these firms also provide the services that are associated with importing. These services include search and acquisition, transportation, logistics, and storing. A major characteristic of this firm type is that it deals primarily in imported goods. This suggests that the procurement of imported goods by firms is a unique process separate from the procurement of similar products produced domestically. Even if the firm is a subsidiary or branch of a larger firm that purchases domestic and foreign-produced inputs, it is not unlikely that the subsidiary that is responsible for imported inputs deals primarily in this activity. This is because the acquisition of foreign-produced goods is more involved than purchasing domestically produced goods.

If we assume a production function for these firms, then the output of these firms is the imported goods that are sold to other firms and the inputs are the imported goods from the various exporting countries. If we minimize cost subject to this production function, the system of input demand equations resulting from the optimization procedure will be a system of import demand equations. If we assume product differentiation across source countries, then each import demand equation represents the demand for a product from a particular source. This model is specified as follows (expressed in finite log changes):

\[ \bar{f}_x \Delta x_i = \theta^*_i \Delta \rho_i + \sum_{j=1}^{N} \pi^*_j \Delta w_j + e_i. \]

where \( \bar{f}_x = (f_x + f_{x-1})/2 \); \( \Delta x_i = \log(x_i/x_{i-1}) \), and \( \Delta w_j = \log(w_j/w_{j-1}) \); \( x_i \) and \( w_j \) represent the quantity and price, respectively, of imported whey from source country \( i \).

In the second stage, the differential factor demand model is derived, which is used to estimate the system of derived-demand equations where each equation is the derived demand for imported whey from a particular source. This model is specified as follows (expressed in finite log changes):

\[ \Delta X_i = \sum_{j=1}^{N} \bar{f}_x \Delta x_i. \]

where \( \Delta X_i \) is the finite version Divisia volume input index; \( \theta^*_i \) and \( \pi^*_j \) are parameters to be estimated; \( n \) is the number of inputs in the system; and \( e_i \) is the disturbance term.

In addition to the imports from each individual source country, labor and other inputs are used in the production process. The labor demand and demand for other inputs are expressed in general terms as

\[ \text{Labor} = f(\text{output, wages, input price index}) \]

\[ \text{Other inputs} = f(\text{output, wages, input price index}). \]

Equations (16) and (17) represent the system of derived-demand equations for labor and other inputs where these inputs are a function

of the total amount to be supplied, wages, and an input price index that represents the price of all inputs except labor and whey imports. Here we assume that labor and other inputs are independent of the source-specific whey imports. This is to say that, although labor and other inputs affect the total to be imported, these inputs do not directly affect the amount imported from an individual source country.

Empirical Results

Using United Nations Commodity Trade Statistics, the derived demand for imported whey into Japan was estimated. The exporting countries considered were the United States, European Union, Oceania (aggregation of Australia and New Zealand), and rest of the world (ROW), which is an aggregation of all other countries. The time period for the data set was 1976–1998. During this period, the United States on average accounted for 35% of all whey exports to Japan, while Oceania, the European Union, and ROW accounted for 17, 19, and 27%, respectively. All values and quantities were reported through Japanese customs. Values were on a cost, insurance, and freight basis. According to FAO statistics, Japan primarily imports dry whey, which is used as both cattle feed and an ingredient in infant formula. In the last decade, imports of dry whey have accounted for 100% of all whey imports.

First-stage estimation required the domestic wholesale price of whey in Japan. This price series was not available. However, a proxy was used that was the per unit wholesale price of all milk powders, which is reported by the Statistic Bureau Management and Coordination Agency for the Government of Japan. To account for the labor requirement in the importation of whey, an index of Japan’s hourly wages was included in the estimation (U.S. Department of Labor). To account for other inputs, an industry input price index was also included (Economagic.com).

Second-Stage Estimation and Conditional Elasticities

Table 1 presents the log-likelihood values, the likelihood ratio (LR) statistics, and the critical value for the LR test for autocorrelation. A likelihood ratio test indicated that first-order autocorrelation could not be rejected at the .05 significance level; thus, all results presented have the AR(1) error structure imposed.*

LR tests were also used to test if the data satisfied the economic properties of homogeneity and symmetry. The results of these tests are summarized in Table 2. LR tests indicate that the property of homogeneity could be rejected. However, Laitinen’s test for homogeneity, which is a more precise test, indicated that homogeneity could not be rejected. Given the homogeneity constraint, symmetry could not be rejected. The property of negative semidefiniteness was verified by inspection of the eigenvalues of the price coefficient matrix. This property is validated when all of the eigenvalues are less than or equal to zero. All eigenvalues were nonpositive in the Japan whey system.

Table 3 presents the conditional parameter estimates for the derived demand and consumer demand for imports of whey into Japan. With the exception of the ROW, all own-price coefficients are negative and all are significant by at least the .05 significance level. The condition marginal factor share estimates indicate

* The AR(1) process is the same for all equations in the system.

A positive relationship between the Divisia volume index of all imports and the imports from the individual sources except for the ROW. In the consumer demand (Rotterdam) model, the conditional marginal factor shares are interpreted as the conditional marginal expenditure share. Cross-price parameter estimates indicate that the U.S. and Oceania whey imports, Oceania and E.U. imports, and E.U. and ROW imports are substitutes.

Table 4 presents the conditional elasticities for the derived demand and consumer demand of imported whey. The Divisia index elasticities for imports of whey into Japan are 0.914, 2.295, 2.336 and −0.500 for the United States, Oceania, the European Union, and the ROW, respectively. These indicate that, as the Divisia volume index increases, imports from the United States will increase proportionately while imports from Oceania and the European Union will increase by more than twice as much. In the consumer demand model, these are interpreted as conditional expenditure elasticities. The own-price elasticities are −1.031, −2.930, −1.574, and −0.296 for the United

States, Oceania, the European Union, and ROW, respectively. With the exception of the ROW, all are significant at the .10 significance level. Conditional cross-price elasticities of derived demand for whey in Japan indicate significant substitutability relationships between whey imports from the exporting sources. The U.S./Oceania cross-price elasticity is 1.003, while the Oceania/U.S. elasticity is 2.106, reflecting the higher value placed on U.S. whey. The Oceania/E.U. and the E.U./Oceania elasticities are 0.441 and 0.401, respectively, indicating fairly equal substitutability between the two sources. E.U. whey imports are the only imports that were substitutes for whey from the ROW.

First-Stage Estimation and Unconditional Elasticities

First-stage estimation required the estimation of equation (14), which is the output supply equation. Results are presented in Table 5. The output price parameter estimate (1.2963) is positive as expected and significant at the .01 significance level. This estimate is also the price elasticity of supply, which indicates that the supply of whey in Japan is price elastic.

Parameter estimates for all import prices are insignificant. The parameter estimate for the price of labor and the price of other inputs ($-1.4888$ and $-3.3351$, respectively) are negative and significant, indicating that wages and other input prices are inversely related to the output supplied, which is to be expected. These are also the elasticity of output supply with respect to the price labor and with respect to the input price index. These indicate that the supply of imported whey in Japan is relatively sensitive to wages and other input prices. First-stage estimation in the differential production model is possible, and correct estimates could be used to derive unconditional derived-demand elasticities.

Unconditional elasticities for the Rotterdam model and the unconditional derived-demand elasticities are presented in Tables 6 and 7, respectively. To derive the unconditional income elasticities for the consumer demand (Rotterdam) model (equation (4)), the income elasticity for the product group whey was estimated to be one.12 For the unconditional own-price/cross-price elasticities (equation (5)), it is assumed that the price elasticity of the demand for the product group is $-0.40$ (Zhu, Cox, and Chavas). Unconditional derived-demand elasticities were derived using equations (11), (12), and (13).

In comparing the unconditional Rotterdam elasticity estimates in Table 6 to the unconditional derived-demand elasticities in Table 7, the biasedness due to the inappropriate application of consumer theory to import demand analysis becomes clear. First, the elasticity of derived demand with respect to output prices, the elasticity of derived demand with respect to wages, and the elasticity of derived demand with respect to other input prices would not be considered if the consumer demand model were applied. These derived-demand elasticities suggest that the derived demand for whey is highly responsive to these factors.

In addition to not reporting some of the derived-demand elasticities, the Rotterdam model leads to substantial differences in the unconditional own-price/cross-price elasticities. In the case of the own-price elasticities, the Oceania and E.U. elasticities derived using the Rotterdam model are substantially larger in absolute terms than the derived-demand

12 The income elasticity for the group whey was estimated using the Workings Model (Theil and Clements, p. 14). The income elasticity for the group whey was equal to one.

elasticiities. In the case of the own-price elasticity of demand for Oceania whey, the Rotterdam model overstates the own-price effect by 1.6 percentage points.

Unconditional cross-price elasticiities differ between the approaches as well. Of the 12 unconditional cross-price elasticiities, 11 are significant in the derived-demand model while 8 are significant when using the Rotterdam model. Five cross-price elasticiities actually change signs (United States/European Union, Oceania/ROW, European Union/Oceania, European Union/ROW, and European Union/United States). The largest difference occurred with E.U./Oceania elasticity, which was estimated to be \(-0.534\) in the Rotterdam model and \(1.114\) in the derived-demand model. Using the Rotterdam elasticiities, one would assess that E.U. whey and Oceania whey were complements, while the derived-demand model indicates a substitutional relationship.

**Summary and Conclusions**

The primary objective of this article was to compare and contrast the use of the differential production approach with the Rotterdam model. Given the intuitive and conceptual appeal of a production approach to import demand analysis instead of a consumer approach (the Rotterdam model), this article investigates the empirical differences due to approach selection. When one compares the conditional derived-demand to the conditional consumer demand system, there is no empirical difference. However, when comparing the unconditional derived-demand elasticiities with the unconditional consumer demand elasticiities, significant differences emerge. This is due to the differences in the first-stage estimation procedure between the two approaches. In fact, first-stage estimation using the Rotterdam model is often not accomplished due to difficulty in defining product groups that make up the first stage. However, in this study, it was shown that first-stage estimation is possible with the production approach and leads to unconditional elasticity estimates. One empirical difference is that, with the production approach, the derived-demand elasticiities with respect to output price, wages, and other input prices are derived. This is not the case with the Rotterdam model. In comparing the consumer demand own-price/cross-price elasticiities with the derived-demand own-price/cross-price elasticiities, it is clear that use of the Rotterdam model when a production approach should be used can lead to overestimation, underestimation, incorrect signs, and erroneous insignificance when deriving the unconditional price effects.
