ECONOMIC CHARACTERISTICS OF CONCRETE PRODUCTION FROM FLY ASH AS A WAY OF LAND RECLULTIVATION

Vladislav Zekić, Nedeljko Tica, Dragan Milić, Zoran Bačkalić

Summary

Application of fly ash in the construction industry is particularly significant in the terms of environmental protection and in the terms of improvement opportunities of certain properties of cement mortar and concrete. In addition to this, it is possible to perform the recultivation of significant area of agricultural land. Concrete production precedes the production of lightweight aggregate which is then used as an aggregate. Calculated costs of concrete production using lightweight aggregate were 70.52 €/m³. Most of these costs are energy costs in the sum of 83% of total costs. In the situation when the costs of concrete production using lightweight aggregate are compared to the concrete price at the market, or produced with the use of construction gravel, estimation of the economic viability gives a negative result. This result is caused by the high cost of the aggregate. The observed calculation did not include an improved thermal-insulating property of concrete and reduce pollution through binding of waste ash. According to this, final assessment can only be made after extensive technological, macroeconomic and environmental analysis. Economic analysis should be primarily based on the value of land that can be recultivation in this way.

Key words: fly ash, agriculture land, recultivation, concrete production.

JEL: Q32, R51

The main limiting factor in the development of human society is the reduction of reserves of non-renewable mineral resources and energy, where agricultural land is particularly important. Land is one of the most important natural resources. Plants which were bred on agricultural land are transforming solar energy into food and raw materials. In addition, preservation of soil to protect genetic resources and all forms of life on our planet purify and detoxify the water. The land is in the interaction with the atmosphere through absorption and broadcasting in gaseous and solid state. Land Conservation provides essential habitat for humans, plants and animals and contributes functioning and stability of the food chain. In this way, it protects the diversity of life, affecting the global cycles and balance on Earth ( Hadžić et al, 2002). Land users, policy makers and the research community, can foster perceptions that degradation of land is the problem that does not directly apply to them (Dalal Clayton, Bass, 2009).

This leads to the development of environmental awareness on a global level, although this is not yet sufficient to achieve a significant impact on the objectives of development, which are still determined by the need for constant growth in consumption. Better knowledge of the change of living environment, with the climate change as most significant, leads to the concern of humankind over the issue of their survival. The modern lifestyle requires a large amount of easily available and cheap energy. A significant part of the environmental problems is related to the construction, maintenance and use of facilities. According to estimates, about 50% of the total energy produced is consumed in residential and commercial buildings. Of that, 69% of the energy is consumed in temperature maintaining and ventilation, 15% for water heating, the lighting and electrical devices about 11% and 5% for cooking. The largest emitters of greenhouse gases are the United States and China. Whereas the U.S. comprises 5% of the world population, but currently spend about 26% of the total energy. The growth of China argues its high percentage of emissions through its recent industrial development, and while other countries developed and polluted, they were not big emitters. China and the overall Asia are currently in an economic expansion, but also turning to the production system for the use of renewable energy sources, in order to be competitive and participate in the global market (http://esttp.org/cms). In China large amount of construction sites, leads to the deterioration of land resources and other environmental problems (Gar On Yeh, Li, 1999).

Proper management of the construction industry is of great importance since it consumes 60% of the raw material extracted from the lithosphere, and the construction goes 24% of a given amount (Wadel, 2009). In addition, previous studies have shown that the construction industry has to uphold sustainability in a great extent and to always take into account the impact on the environment (Speth, 1990; Ehrlich, Ehrlich, 1990) especially when it comes to the destruction of agricultural land.

Amounts of fly ash generated by burning coal in power plants are both in the world and in Serbia, serious economic but primarily environmental problem. Amount of ash that is deposited annually is measured in millions of tones. In Serbia every year occur between 6 and 7 million tons of fly ash. Fly ash landfill covers significant areas of arable land,
about 1800 ha (http://www.eps.rs/ ecology/zastita.htm). Currently in Serbia, as well as in the world, only a portion of the produced fly ash is used as a pozzolanic additive in cement and concrete (Ilić et al., 2003). Exploitation of this waste as secondary raw materials in the production process imposed as the only viable solution. It is clear that such large quantities of fly ash can only be used in the construction and building materials industry (Baščarević et al., 2006).

Material and methods

Analysis of the economic characteristics of the plant for the production of concrete is based on the calculation of the investment. It is performed on the basis of the preliminary technical - technological project. Since it is not possible to determine the market price of the lightweight aggregate, costs of production are used in the calculation (Zekić, Bačkalić, 2013). Cost calculation is based on determining the total cost (Jakovčević, 2008). Amortization is calculated in accordance with the estimated investment and superior shelf life of certain assets. Salaries were calculated according to the average wage in the Republic of Serbia, in accordance with the required qualifications. The costs of consumed energy are determined in accordance with the pending charges and market prices. The cost of maintaining the facilities and equipment are accounted by empirical standards. The opportunity cost of financing and land use and insurance costs are not calculated.

Results and discussion

The scientific understanding and prevention of the land degradation in the past are based on understanding institutional, sectoral, financial, legal and scientific obstacles. On the other hand, it is clear that the degradation of agricultural land is an obstacle to the creation of the sustainable development of society. The solution to these problems includes several sectors and disciplines (Akhtar Schuster et al, 2011).

Construction industry is greatly responsible of land degradation. The problem of preservation and reclamation of agricultural land must be viewed through the development of sustainable technologies in the production of building materials. Land degradation cannot be judged separately of its economic, environmental and cultural context (Warren, 2002).

Concrete is the most widely used construction material. Concrete is a construction material that is made of cement, aggregate or gravel and sand and water. The term “concrete” means a broad range of artificial construction materials of the composite type which are obtained by agglomeration of the different types of grain aggregates. Undoubtedly, widest application has concrete where the cement is used as a binder. Concrete is a material that is the most used of all artificial materials in the world. It is used for making roads, building, foundations, bridges, blocks, etc. Using waste materials in concrete production can reduce the currently very prominent problem of waste. One of the potentially reusable wastes is fly ash from power plants. During the combustion of ground coal in boilers of thermal power plants, ash particles that come along with the flue gases are collected in electrostatic filters. This is called a fly ash and represents approximately 85% of the total amount of ash in thermal
power plants. Fly ash has specific characteristics that are significantly different from other industrial by-products used as additives in the cement industry. Beside this, variations of these characteristics are much higher than, for example, of the blast furnaces or filter SiO2 dust, because they depend on the type and quality of used coal and technological conditions of burning (temperature) and cooling mode of fly ash particles (Baščarević et al., 2006). World production of fly ash is about 700 million tons per year, while only 6% of this waste material is used in the production of cement (Jozić, 2007; Wong et al., 2004) while the remaining disposed with almost irreversible destruction of agricultural land. In addition, it is used for roads, as a fraction of the support layer, making building bricks, ceramics, glass ceramics and tiles and for the stabilization and solidification of industrial waste (Jovanović et al., 2006). Amounts of ash in this way consumed are insufficient for a permanent solution to the problem of ash landfills so that in each case it is necessary to look for a new ways of use so the use of fly ash as a construction material should be the primary purpose.

The selection of construction materials for certain purposes, as a rule, is carried out on the basis of the functional, technical and financial size. However, the introduction of the concept of sustainability and sustainable development as well as decision-making criteria in the past few decades changed the classical approach to the evaluation of building materials.

Wide application of fly ash as a raw material for the production of building materials, in addition to the above mentioned benefits, to some extent could influence the reduction of unemployment in rural areas where the landfill of ash is typically found. The unemployment problem in the past was latent and concealed within social enterprises and family farms. Today, changes in the social system and the ownership structure of the economy make unemployment prominent problem. The answer to the problem of unemployment among the rural regions is necessary to find in the specific form of rural development (Zekić, Ranogajec, 2012).

Economic analysis of concrete production involves the use of lightweight aggregate which should gain concrete with improved thermal insulation properties (Zekić, Bačkalić, 2013). Concrete production is based on the composition and cost of materials required for making of concrete brand 20 given in the following table.

In line with the aim of research is projected plant for the production of concrete using lightweight aggregate with capacity of 80 t/h. Total investment in the plant for the production of concrete is approximately 2.6 million €, of which 1.45 million € is for equipment, while 1.15 million € makes investments in facilities and utility equipment. The calculation of amortization costs is shown in the following table.

An estimation of the observed technology can be made only by a complete investment analysis. Only in this way it is possible to reach the value of investments that an investor can invest in a given plant, or costs of production that can be covered by the revenues.

Plan of the plant work is based on the duration of the shift from 7.30 h, six working days a week, two production shifts per day. The plan includes one shift a week for overhaul. In accordance with this, plan includes 11 production shifts per week and fifty working weeks in a year. Calculation of costs for salaries plans constantly engaging 9 people. The calculation of salary costs is shown in the following table.

Source: calculation by authors

The total planned production is 33,000 m³. Based on the planned production and actual expenses can be derived basic economic indicators. The amount of calculated costs of concrete production using lightweight aggregate are 122.95 or 123.59 €/m³. In doing so, most of the costs are the costs of materials, which in the sum are over 99% of total costs. In the situation when the costs of concrete production using lightweight aggregate are compared to the concrete price at the market, or produced with the use of construction gravel, estimation of the economic viability gives a negative result. This result is caused by the high price of used units. Price of construction gravel on the market is 18.00 €/t, which is much lower compared to the lightweight aggregates.

Conclusion

One of the ways to ensure the preservation of the environment is to use materials that are by-products of energy production, as aggregate for mortar and concrete. The use of waste materials not only affects the reduction of environmental pollution, but also has an impact on society resources conservation, because it reduces the exploitation of raw materials and provides a substitute for materials like cement, whose manufacture requires significant amounts of raw materials, energy and resources to produce.

The use of fly ash as a raw material for the production of building materials has a number of advantages: 1) permanently solves the problem of waste and the deterioration of agricultural land, 2) reduces the depletion of other natural resources, 3) creates a basis for energy efficiency through substitution of cement, 4) the recycling process is flexible since the waste can be easily stored and used for several purposes. Therefore, the use of fly ash in building materials and concrete technology solves the problems of industrial waste, environment pollution, the destruction of thousands of acres of land. In doing so, it also offers the possibility of creating new cost-effective building materials. In addition, the economic results should be interpreted bearing in mind that the calculations are evaluated...
using the possible recultivation of agricultural land. The consequences of certain types of land degradation can be catastrophic if we forget that the land is one of the most important and irreplaceable resource on earth. Environmental sustainability puts agricultural land at the centre of any development strategy. For this reason, conservation, protection and rational use of agricultural land should be at the centre of any development strategy. There is an urgent need to solve this problem, bearing in mind the trends in increasing land degradation and its links with climate change, biodiversity loss, poverty, health, food, water and energy and general uncertainty.

The production costs of concrete obtained with the use of lightweight aggregates is significantly higher than the current market price. In accordance with this, current application of concrete the produced in the described manner is not economical. During this assessment it is necessary to bear in mind that the calculation did not include the observed enhanced thermal-insulating properties of concrete and pollution reduction through binding of fly ash. In accordance with this final assessment can only be made after extensive technological and macroeconomic analysis.
