Paper prepared for presentation at the EAAE 2014 Congress
‘Agri-Food and Rural Innovations for Healthier Societies’

August 26 to 29, 2014
Ljubljana, Slovenia
This work deals with issues of multiperiod hedging ratio (MHR). We derive an analytical formula for the MHR starting from the triangular representation of a cointegrated system. Secondly, using both overlapping and non-overlapping price changes we investigate the properties of OLS MHR. Thirdly, we resort to simulated data to investigate the performance of MHR estimators. Unlike previous studies, we do not use real data whose data generating process is unknown; instead we run a Monte Carlo exercise to investigate estimators and compare them with theoretical measures. Finally, we apply our approach to real data for a hedging related to soft wheat.

Keywords: Futures prices, Hedging, Monte Carlo simulation, Soft wheat

Introduction

The rationale behind this article stems from a practical problem faced by the food industry and cereal producers in a particular EU region when implementing forward contracts along the bread food chain. The contracts offered by the industry provide farmers with a hedging instrument through which they can reduce the price risk they face. In its own turn, the food industry needs to hedge with futures the price risk it assumes when issuing forward contracts. As the forward contracts with farmers need to be signed in October to expire the following June, the hedging horizon spans more than 6 months. We hypothesize that the food industry can cross-hedge its long term buying commitment by selling soft wheat futures contracts exchanged on the French MATIF (Marché a Terme Internationale de France). The described risk managing problem calls for an estimation of the optimal hedging ratio (OHR) based on the available weekly prices. Most of the studies on hedging deal with the derivation of OHR under different utility functions or the methodological aspects of OHR estimation under different hypotheses about the data generation processes (DGP) behind the observed price series. However, as noted by Chen, Lee and Shrestha (2004: 360) many empirical studies “ignore the effect of hedging horizon length on the optimal hedging ratio and hedging effectiveness”.

Indeed, in spite of such interest on broad hedging issues, literature concerning the relationship between the hedge ratio and the hedging horizon has been scanty, even though it appears to have important implications for the use of derivatives in commodity hedging.

The first issue that emerges from the literature is the sensitivity of results to how the relationship between spot and futures prices is modeled.

In addition, in order to validate the models, theoretical measures are often compared with empirical estimates on real spot and futures series. However, unless we are sure that our model truly represents the DGP underlying the observed real data, we cannot use real data to compare or validate alternative estimates of the hedging ratio against the results from the formula analytically derived within our model. The question of which estimator of the multiperiod OHR provides the best unbiased and efficient estimates should be addressed only when working with data generated by the very model which provides a benchmark measure for the hedging ratio.

Hypothesizing a given DGP which is not supported by the data leads to misspecified estimators of the OHR even though this approach may prove useful to get an idea of how MVHR and HE evolve with the hedging horizon. To this purpose the model should be as simple as possible whilst still accounting for the basic features of real data such as cointegration.

The use of real data gives rise to a second methodological issue: to get empirical estimates it is necessary to match the frequency of data with the hedging horizon, whereupon we face the problem of sample size reduction. Indeed, a trade-off arises between working on
overlapping observations thereby maintaining an adequate sample size as the hedge horizon lengthens, but inducing a moving average process in OLS residuals, or else resorting to non-overlapping observations, thus facing a dramatic reduction in sample size for longer hedging horizon. Authors differ widely in the solutions they propose.

We contribute to this literature in three ways. Firstly, we derive an analytical formula for the multiperiod minimum variance hedging ratio (MVHR) starting from the triangular representation of a cointegrated system, a representation that has not yet been explored in this context. Secondly, using both overlapping and non-overlapping price changes we investigate the properties of OLS or textbook MVHR estimators and discuss the sample reduction problem for longer hedging horizons. Thirdly, we resort to simulated data to investigate the performance of MVHR estimators. In contrast to previous studies, we do not use real data whose DGP is unknown; instead we run a Monte Carlo exercise to investigate our estimators and compare them with the theoretical measures. Only after that do we estimate the hedging ratio on real data and discuss results in the light of the outcome of the previous steps.

Our work differs from previous studies since it consistently explores the behaviour of hedging ratio estimators within the hypothesized DGP which provides benchmark measures. In addition, Monte Carlo simulations allow us to explore the performance of hedging ratio estimators when the sample size lengthens without the interference of confounding factors which may appear in real data.

The model: a prototypical ECM

As in Jhul, Kawaller and Koch (2012), we consider a cross hedge with a price \( y_t \) for a commodity at the time it will be delivered to a given location and the corresponding futures price \( x_t \) for future delivery of the same commodity to a different location. We assume that the two prices are cointegrated with \( x_t \) weakly exogenous. To make analytical derivation simpler, we also assume that the futures price is a purely random walk.

The vector error correction representation of the cointegrated system is thus given by:

\[
\begin{align*}
\Delta y_t &= \alpha (y_{t-1} - \beta x_{t-1}) + \nu_t \\
\Delta x_t &= \varepsilon_t
\end{align*}
\]  

(1)

where \( \varepsilon_t \) and \( \nu_t \) are jointly white noise, possibly contemporaneously correlated. Differently from Lien (1992) and Juhl, Kawaller and Koch (2012) we reparameterize the vector ECM in (1) to the Phillips’s (1990) triangular representation of the cointegrated system:

\[
\begin{align*}
y_t &= \beta x_t + u_t \\
x_t &= x_{t-1} + z_t
\end{align*}
\]  

(2)

with \( u_t \) and \( z_t \) \( I(0) \) processes given by:

\[
\begin{align*}
u_t &= \phi u_{t-1} + \eta_t \\
z_t &= \varepsilon_t
\end{align*}
\]  

(3)

with \( \phi = 1 + \alpha \) and \( \eta = \nu_t - \beta \varepsilon_t \).

Note that, as \( u_t \) follow an AR(1) process we get:
The triangular representation facilitates both simulations of the cointegrated system and
derivation of a formula for the MVHR. The resulting model is close to the one employed by
Jhul, Kawaller and Koch (2012) although under a different parameterization and without
the restriction of the cointegration coefficient $\beta$ being equal to 1.

According to Ederington (1979), the MVHR, also known as the “textbook solution”, is
given by:
\[
MVHR(k) = \frac{\text{Cov}(\Delta_k y, \Delta_k x)}{\text{Var}(\Delta_k x)}
\]  

where $\Delta_k$ is the difference operator over $k$ periods.

We are interested in comparing the performance of simple OLS estimators of MVHR($k$)
using the Ederington unconditional HE measure. However, we note that when $x_t$ follows a
random walk, conditional and unconditional hedge ratios are equal (Lien 2005).

MVHR can be easily expressed as a function of the triangular representation parameters
for different values of $k$.

After some relatively straightforward algebra (see Appendix A) we get:
\[
MVHR(k) = \frac{\sigma_{uc}^2 + \beta \sigma_z^2 + \beta \sigma_e^2}{k \sigma_z^2}
\]

which for $k=1$ gives the short horizon hedge
\[
MVHR(1) = \frac{\sigma_{uc}^2 + \beta \sigma_z^2 + \beta \sigma_e^2}{k \sigma_z^2}
\]

while for $k \to \infty$ the limit of (5) is $\beta$, that is the long term hedge ratio (as in Chen, Lee and
Shrestha (2004)).

The Ederington HE measure is given by (see appendix A):
\[
HE = \frac{k \beta \sigma_z^2 + \sigma_{uc}^2 \left(1 - \phi^k\right) + \frac{\beta \sigma_z^2 + \beta \sigma_e^2 +\frac{1}{1-\phi} \beta \sigma_e^2}{2 \left(1-\phi^k\right) \sigma_u^2 + k \beta \sigma_z^2 + 2 \frac{1}{1-\phi} \beta \sigma_e^2}}{MVHR(k)}
\]

whose limit for $k \to \infty$ is $1^2$, as in Geppert (1995) and Juhl, Kawaller and Koch (2012).

Summing up, the analytical derivation of MVHR($k$) for cointegrated prices under
the triangular representation parallels the results of models developed under other representations
(ECM or common trend) with a relatively more straightforward algebra. In addition, the
triangular representation is particularly convenient to simulate the series as it will be
illustrated in the next section.

**Monte Carlo Analysis**

\[
\sigma_u^2 = \frac{\sigma_e^2}{1-\phi^2} = \frac{\sigma_y^2 + \beta^2 \sigma_z^2 + 2 \beta \sigma_e^2}{1-\phi^2}
\]

\[
\sigma_z^2 = \sigma_y^2
\]

\[
\sigma_{uc} = \sigma_e^2 - \beta \sigma_z^2
\]
We run Monte Carlo simulations from the triangular representation of a cointegrated system given in equations (2) and (3). We start from the ECM parameterization and generate a bivariate error series from a bivariate normal with parameters:

\[
\begin{bmatrix}
\begin{pmatrix}
\mu &= \begin{bmatrix} 0 \\ 0 \end{bmatrix} \\
\Sigma &= \begin{bmatrix} 10 & 6 \\ 6 & 30 \end{bmatrix}
\end{pmatrix}
\end{bmatrix}
\]

Then, we generate the error series \( \eta \) in the triangular representation as:

\[
\eta = u_t - \beta \epsilon_t
\]

with the parameter \( \beta \) set to 0.92. Next, the error \( u_t \) in equation (3) is simulated as an AR(1) process with innovations \( \eta \) and parameter \( \phi = 1 + \alpha \) set to 0.88. All parameter values are chosen in the proximity of values obtained by estimating the system equations (1) with real data on Italian wheat spot and French MATIF futures prices.

We then take both the overlapping and the non-overlapping \( k \)-period differences of the simulated series and estimate the linear model:

\[
\Delta_k y_t = \alpha + \beta \Delta_k y_{t-1} + \varepsilon_t \quad \text{for } t=1 \ldots T
\]

We run Monte Carlo simulations using a variety of values for hedging horizon \( k \) and for the sample period \( T \) resulting in different scenarios. The sample period \( T \) ranges from 360 to 2880. Although series of double that length are actually generated (from 720 to 5760), the first half of which are employed to estimate \( \beta \), and the second half to recover an out-of-sample HE measure.

The hedging horizon ranges from 1 to 36 weeks. For each scenario and for each draw, we then take both the overlapping and the non-overlapping \( k \)-period differences of the simulated series and estimate the linear model:

\[
\Delta_k y_t = \alpha + \beta \Delta_k y_{t-1} + \varepsilon_t
\]

We report the bias, standard deviation and root mean squared error (RMSE) of OLS estimates of \( \beta \), as well as the related OLS standard error and \( R^2 \) estimates. For overlapping observations we also report the truncated kernel autocorrelation consistent standard errors (HAC) in order to take into account the autocorrelation of OLS residuals.

In table 1 we report estimates for overlapping observations. As expected, both hedge ratio and \( R^2 \) increase with \( k \), the hedging horizon. Estimates exhibit a small downward bias, which grows with \( k \) but decreases to negligible values with \( T \), the sample size. As expected, OLS standard errors are not appropriate because of the induced serial correlation of the OLS residuals. HAC standard errors, in this case, provide a better approximation. \( R^2 \) and out-of-sample HE show close values as expected given that the same DGP underlying both in sample and out-of-sample observations.

Table 2 reports values for non-overlapping observations that basically show the same pattern seen in the overlapping case with respect to \( k \) and \( T \). However, non-overlapping observations exhibit higher \( \beta \) values and \( R^2 \) values although the difference shrinks with higher values of \( T \). Interestingly, non-overlapping observations exhibit a lower bias, this time upwardly. Finally, the difference between the overlapping and non-overlapping estimates of \( \beta \) and \( R^2 \) decreases as the sample period \( T \) increases.

The most striking difference between OLS estimates with overlapping and non-overlapping observations is the strong rise in the Monte Carlo standard deviation of \( \beta \) that we observe with non-overlapping observation. For higher values of \( k \) and lower \( T \) standard deviation of \( \beta \) is more than double when estimated with overlapping observations. Figure 1
illustrates both the pattern of $\beta$ mean estimates and variability as $k$ varies in the case of the smaller and the larger sample sizes employed in the Monte Carlo exercise. It is clear that the OLS estimates of MVHR on non-overlapping observations are far less efficient when $T$ is small and $k$ large. This comes as no surprise since Hansen and Holdrick (1980) and Holdrick (1992) demonstrate that the asymptotic standard errors for $\beta_{ov}$ are smaller than those for $\beta_{non-ov}$.

Note: Vertical bars are at 2 standard deviation above and below the mean values.

Note: $T$ is the length of the simulated series, the number of available observations for OLS is given by $T/k$.

An Empirical application: Italian spot price and MATIF wheat futures

We consider a cross hedge for soft wheat: the two locations for spot and for the commodity specification underlying the futures contracts exchanged on the MATIF market are respectively Bologna (Italy) and Rouen (France). The futures contract used in the article is the nearest-to-maturity contract and it is rolled over to the next contract on the first day of the month when the contract expires. In order to see the impact of the length of hedging horizon, the same data frequencies used in the previous section (ranging from 1 to 36 weeks) are examined. Data are weekly prices from the 2nd week of 2000 to the 47th week of 2012 amounting to 670 observations.

ADF test and KPSS test highlight that both the futures and spot prices are I(1). Johansen trace test for cointegration reveals the presence of one cointegrating vector. In addition, estimates of the cointegrating vector and loading coefficients (coefficients of the error correction term in the spot and futures price changes equations) confirm that futures prices weakly exogenous as previously hypothesized.

We then go on to estimate the ECM for the spot price change in order to obtain the coefficient of the lagged error correction term to be used in the Monte Carlo exercise.

Hedge Ratios and Hedging Effectiveness

The results of the hedge ratios for various hedging horizon lengths are shown in table 6. The hedge ratio (the $\beta$ coefficient) increases with the hedging horizon. Noticeably, the hedge
ratios for longer horizons are larger than the futures coefficient in the long term relationship which is 0.92. This contradicts the findings of the modelling section concerning the limit of the MVHR when the hedging horizon grows to infinity. This evidence points out how misleading it can be to validate a theoretical model for MVHR with data that do not strictly follow the assumed DGP, a danger we avoided by using data from a Monte Carlo simulation.

Non-overlapping hedge ratios are slightly higher than overlapping hedge ratios and do not grow monotonically with \( k \) (figure 2): a feature already observed by Geppert (1995). Non overlapping standard errors are sensibly higher confirming the findings by Hansen and Hodrik (1980) about sample size reduction associated with non overlapping observations reducing efficiency in OLS estimates. In addition, \( R^2 \) statistics for longer horizons is well above 0.80, which is considered by the US accounting standards to be a condition for hedging to be effective in offsetting a particular exposure (see Juhl, Kawaller and Koch 2012). At least in the overlapping case, the overall pattern of evolution of MVHR estimates as the hedging horizon grows is similar for both real and simulated data. In particular, MVHR shows a monotonic increase in both cases, with diminishing increments as \( k \) grows.

Figure 2. Overlapping vs non overlapping OLS estimates of MVHR: real data.

Conclusions
This article has dealt with both methodological and empirical issues concerning the multiperiod OHR. Hypothesizing a given DGP, when the data do not actually follow it, leads to misspecified estimators of the OHR even though this approach can be useful to have an idea of how MVHR and hedging effectiveness evolve with hedging horizon. To this purpose, we have proposed analytical formula for the multiperiod MVHR starting from the triangular representation of the cointegrated system DGP.
In addition, empirically estimating the OHR matching the frequency of data with the hedging horizon leads to the problem of sample size reduction. Thus, we have proposed a Monte Carlo study to investigate the pattern and hedging efficiency of both overlapping and non-overlapping OLS hedging ratios for different hedging horizons and different sample sizes.

Finally, we have carried out our empirical estimation of the hedging ratio by considering a cross hedge scheme for soft wheat, with futures contracts exchanged on the French MATIF market.

The Monte Carlo exercise shows that, as expected, both hedge ratio and $R^2$ increase with the hedging horizon. OLS standard errors with overlapping observations are not appropriate because of the induced serial correlation of the OLS residuals. Interestingly, the difference between the overlapping and non-overlapping estimates of beta and $R^2$ increases as the sample period decreases.

The most striking difference between OLS estimates with overlapping and non-overlapping observations is the strong rise in the Monte Carlo standard deviation of hedge ratios that we observe with non-overlapping observation. Thus, it becomes clear that the OLS estimates of MVHR on non-overlapping observations are far less efficient when sample sizes are small and the hedging horizon long. Non-overlapping hedge ratios are slightly higher than overlapping hedge ratios, while the variance is slightly lower in the latter case. Empirical application with real data reveals again that the variance of the hedge ratios with non-overlapping observations is slightly higher than in the case of overlapping observations, confirming that OLS estimates of MVHR with robust standard error on overlapping observations are more efficient when the hedging horizon is long and the sample size not sufficiently large.

As our article differs majorly from previous studies, since it consistently explores the behaviour of MVHR estimators within the hypothesized data generating process, not only eliminating the sample size reduction problem but actually exploring the performance of hedging ratio estimators when the sample size varies, we think that this article succeeds in highlighting and clarifying some methodological and empirical issues related to multiperiod hedging.

Indeed, the double estimate with simulated and real data have highlighted how misleading it could be to validate a theoretical model for MVHR with data that do not strictly follow the assumed DGP. The Monte Carlo exercise enabled us to avoid such danger.

However, we think that this article mainly provides a practical contribution to hedging activities. Indeed, the results we have obtained allow us to give preference to results with robust variance and covariance estimates for overlapping observations instead of estimates for non-overlapping ones. The problem of sample size reduction, indeed, appears to be a major issue. Thus, we think we have provided a real compromise between sophisticated methods against sample reduction (e.g. wavelet analysis) and straightforward estimations: we think that such a compromise could be particularly useful for hedgers.

Notes
1 For example: $\Delta_t y_t = y_t - y_{t-3}$ or, equivalently, $\Delta_t y_t = \Delta y_t + \Delta y_{t+1} + \Delta y_{t+2}$.
2 It is sufficient to divide by $k$ both numerator and denominator of the first r.h.s. term of 6 to see that its limit tends to $\beta$ which multiplied by the limit of MVHR (that is $\beta$) gives unity.
3 Monte Carlo results are obtained running 5000 simulations.
4 The hedging effectiveness (HE) is computed as follows: $HE = 1 - \frac{Var(\text{hedged portfolio})}{Var(\text{unhedged portfolio})}$.
5 This estimator was proposed by Hansen and Hodrik (1980).
6 Futures series are obtained from Bloomberg, while spot series are obtained from ISMEA.
7 We have performed the ADF test with drift and trend.
Lags have been selected according to the higher value provided by the Aikake’s AIC, Hannan and Quinn, Schwarz’s BIC, and Lutkepohl final prediction error.

This result is confirmed, for example, in Chen, Lee and Shrestha (2004), Juhl, Kawaller and Koch (2012).

References

Appendix A

Single period Covariances

From equation (1) in the article we get:

\[ \Delta y_t = u_t - u_{t-1} + \beta z_t \]  \hspace{1cm} (A1)

hence

\[ \text{Var}(\Delta y) = 2\sigma_u^2 + \beta^2 \sigma_z^2 + 2\beta \sigma_u \sigma_z - 2 \phi \sigma_u^2, \text{ since } \text{Cov}(u_{t-1}, z_t) = 0 \]  \hspace{1cm} (A2)

Similarly

\[ \text{Var}(\Delta x) = \sigma_z^2 \]  \hspace{1cm} (A3)

and

\[ \text{Cov}(\Delta y, \Delta x) = \sigma_{u\beta} + \beta \sigma_z^2 \]  \hspace{1cm} (A4)

Now we define

\[ \Delta_t x_t = \sum_{i=0}^{k-1} \Delta x_{t-i} \]  \hspace{1cm} (A5)

Multiperiod Covariances

For \( k=2 \) we have:
\[ \text{Var}(\Delta_2 x) = \text{Var}(\Delta x_i + \Delta x_{i-1}) = 2\sigma_z^2 \] (in the general case \( \text{Var}(\Delta x) = k\sigma_z^2 \))\hfill (A6)

while the corresponding expression for \( y \) is
\[ \text{Var}(\Delta_2 y) = 2(1 - \phi^2)\sigma_u^2 + 2\beta^2\sigma_z^2 + 2(1 + \phi)\beta\sigma_{uz} \]
\[(A7)\]

which generalizes to
\[ \text{Var}(\Delta_k y) = 2(1 - \phi^k)\sigma_u^2 + k\beta^2\sigma_z^2 + 2\frac{1 - \phi^k}{1 - \phi} \beta\sigma_{uz} \]
\[(A8)\]

and
\[ \text{Cov}(\Delta_2 y, \Delta_2 x) = \text{Cov}(\Delta x_i, \Delta y_i) + \text{Cov}(\Delta y_i, \Delta x_{i-1}) + \text{Cov}(\Delta y_{i-1}, \Delta x_i) + \text{Cov}(\Delta y_{i-1}, \Delta x_{i-1}) \]
\[= (\sigma_{uz} + \beta\sigma_z^2)(\phi - 1)\sigma_{uz} + 0 + (\sigma_{uz} + \beta\sigma_z^2)(1 + \phi)\sigma_{uz} + 2\beta\sigma_z \]
\[(A9)\]

Similarly we get:
\[ \text{Cov}(\Delta_3 y, \Delta_3 x) = \text{Cov}(\Delta x_i, \Delta y_i) + \text{Cov}(\Delta y_i, \Delta x_{i-1}) + \text{Cov}(\Delta y_{i-1}, \Delta x_i) + \text{Cov}(\Delta y_{i-1}, \Delta x_{i-1}) \]
\[+ \text{Cov}(\Delta y_{i-1}, \Delta x_{i-1}) + \text{Cov}(\Delta y_{i-1}, \Delta x_{i-2}) + \text{Cov}(\Delta y_{i-2}, \Delta x_i) + \text{Cov}(\Delta y_{i-2}, \Delta x_{i-1}) + \text{Cov}(\Delta y_{i-2}, \Delta x_{i-2}) \]
\[= (\sigma_{uz} + \beta\sigma_z^2)(\phi - 1)\sigma_{uz} + \phi(\phi - 1)\sigma_{uz} + 0 + (\sigma_{uz} + \beta\sigma_z^2)(\phi - 1)\sigma_{uz} + 0 + 0 + (\sigma_{uz} + \beta\sigma_z^2) \]
\[= \sigma_{uz}\left[\sum_{i=1}^{3} (3 - i)\phi^{i-1}(\phi - 1)\right] + 3(\sigma_{uz} + \beta\sigma_z^2) \]
\[(A10)\]

which by induction leads to the general case of a \( k \) multiperiod change
\[ \text{Cov}(\Delta_k y, \Delta_k x) = \sigma_{uz}\left[k + \sum_{i=1}^{k} (k - i)\phi^{i-1}(\phi - 1)\right] + k(\beta\sigma_z^2) \]
\[= k\sigma_{uz} + \sigma_{uz}\left[k + \sum_{i=1}^{k} (k - i)\phi^{i-1}(\phi - 1)\right] + k(\beta\sigma_z^2) = k(\sigma_{uz} + \beta\sigma_z^2) + \sigma_{uz}[A] \]
\[(A11)\]

Which, after some algebra on \( A \) (see A12) could be further simplified to:
\[ \text{Cov}(\Delta_k y, \Delta_k x) = k\beta\sigma_z^2 + \sigma_{uz}\left(1 - \frac{\phi^k}{1 - \phi}\right) \]
\[(A11bis)\]

\[ A = \sum_{i=1}^{k} (k - i)\phi^{i-1}(\phi - 1) = \phi(\phi - 1)\sum_{i=1}^{k} \left(1 - \frac{i}{k}\right)\phi^{i-1} = k(\phi - 1)\sum_{i=1}^{k} \phi^{i-1} - k \sum_{i=1}^{k} i\phi^{i-1} \]
\[= k(\phi - 1)\left[\frac{1}{\phi} - \frac{\phi(\phi - 1)}{1 - \phi} - \frac{1}{k}\phi^{k-1} + (\phi - \phi^k)\frac{1 - (k + 1)\phi^k}{(1 - \phi)^2}\right] \]
\[(A12)\]

which, after simple algebra, leads to
\[ A = \left[\frac{1}{k - i + \phi^k} - \phi^k(1 - \phi)\right] \]
\[(A13)\]

**Hedge ratios**
Now we can write the expression for the hedge ratio:

\[ MVHR(k) = \frac{Cov(\Delta_y, \Delta x)}{Var(\Delta x)} = \frac{k(\sigma_{uc} + \beta \sigma_z^2) - \sigma_{uc} \left[ (k - 1 + \phi^k) - \frac{\phi(1 - \phi^k)}{(1 - \phi)} \right]}{k \sigma_z^2} \]

Or, using A11bis:

\[ MVHR(k) = \frac{Cov(\Delta_y, \Delta x)}{Var(\Delta x)} = \frac{k \beta \sigma_z^2 + \sigma_{uc} \left( \frac{1 - \phi^k}{1 - \phi} \right)}{k \sigma_z^2} \quad (A14) \]

The Ederington hedging effectiveness measure is given by:

\[ HE = \frac{\left[ Cov(\Delta_y, \Delta x) \right]^2}{Var(\Delta_y) Var(\Delta x)}, \quad (A15) \]

that is

\[ HE = \frac{\left[ Cov(\Delta_y, \Delta x) \right]}{Var(\Delta_y)} MVHR(k) \quad (A16) \]

where the first r.h.s. term is given by:

\[ \frac{Cov(\Delta_y, \Delta x)}{Var(\Delta_y)} = \frac{k \beta \sigma_z^2 + \sigma_{uc} \left( \frac{1 - \phi^k}{1 - \phi} \right)}{2(1 - \phi^k) \sigma_z^2 + k \beta^2 \sigma_z^2 + 2 \frac{1 - \phi^k}{1 - \phi} \beta \sigma_{uc}} \quad (A17) \]
