Abstract: *The paper develops a framework combining a model of rational behaviour under dietary constraints, an epidemiological model of diet-related mortality, and a life-cycle-analysis model of environmental impact, which permits the ex-ante assessment of dietary recommendations in multiple sustainability dimensions (i.e., taste cost, welfare effect, deaths avoided, reductions in greenhouse gas emissions and acidification). It is applied to compare in a French context the relative effects and efficiency of six popular sustainable diet recommendations. The results confirm the synergies between the health and environmental dimensions: healthy-eating recommendations usually have a positive effect on the environment, although some exceptions exist. Most of the sustainable diet recommendations appear highly cost-effective, but those most commonly promoted on health grounds (e.g., targeting consumption of salt, fruits and vegetables and saturated fat) rank highest in terms of overall efficiency. Moreover, the valuation of benefits indicates that in most cases health benefits are significantly larger than environmental benefits. Overall, the analysis reveals some under-investment in the promotion of sustainable diet recommendations in France. The general lack of enthusiasm in policy circles for informational measures promoting behavioural change may reflect unrealistic expectations about the speed and magnitude of dietary change rather than an objective assessment of the efficiency of those measures.*

1. Introduction

Food consumption patterns observed in developed countries raise two main types of concerns. First, it is widely recognized that the food sector contributes significantly to climate change through high greenhouse gas emissions (GHGEs): from 15 to 30% of total GHGEs are induced by food production, distribution and consumption (Esnouf et al., 2013). For this reason, changes in consumers' diets are often considered as an important driver of climate change mitigation (Hoolohan et al., 2013; Carlson-Kanyama and Gonzalez, 2009; Tukker et al., 2011) and many reports suggest promoting new consumption patterns based on the reduction of meat and dairy consumption and the substitution of meat products by plant-based products within the diets of high-income country consumers (FAO, 2010; Stehfest et al., 2009; Berners-Lee et al., 2012; Friel et al., 2009).

Second, unhealthy diets, in association with physical inactivity, are risks factors strongly related to various chronic diseases, including obesity, strokes, diabetes, and some types of cancers (World Health Organization, 2003). This statement has led many public health agencies to set up prevention policies based on healthy-eating messages and information campaigns (Mazzocchi and Traill, 2011). Most frequent messages promoted by health agencies encourage individuals to adopt healthier diets and consume more

fruit and vegetables (F&V) (Cappacci and Mazzocchi, 2011) and less salt (Shankar et al., 2013). Starchy foods products are other food groups whose consumption is often promoted by public health experts (Mancino et al., 2008), whereas some of them have recommended a decrease in consumption of soft drinks (Jou and Techakehakij, 2012).

As noted by McDiarmid et al. (2012), health and environmental issues need to be tackled together to ensure consistent dietary advice for consumers. Despite the fact that the convergence between health and environmental challenges is not systemically guaranteed (McDiarmid et al., 2012; Vieux et al., 2012; Masset et al., 2014), it is now widely accepted that the reduction of meat consumption and the shift toward plant-based diets would have a favorable effect on both environment and health (Pimentel and Pimentel, 2003; Soret et al., 2014; Berners-Lee et al., 2012; McEvoy et al., 2012; Aston et al., 2012; Scarboroug et al., 2014).

Indeed, on the one hand, red meat is suspected to have a causal influence on colorectal cancer and other forms of cancers and may be associated with cardiovascular diseases because of its high cholesterol and saturated fat acids (SFA) contents (McMichael et al., 2007). On the other hand, plant-based products have much lower impacts on GHGEs than animal-based products (Masset et al., 2014).

Whether for health or environmental benefits, consumers are then more and more urged to make food choices while complying with a whole range of dietary recommendations which target health and environmental benefits. Education and information campaigns and food labeling are implemented in order to induce these dietary changes. However, a lot of research shows that the adoption of new diets by consumers are difficult for many, with campaigns raising, for instance, awareness of nutritional issues without having a large impact on behaviours (Pérez-Cueto et al., 2013).

If several reasons can be proposed to explain the difficulties in changing behaviours, one is related to the "taste cost" of change, that is, the utility loss induced by a dietary change that brings a new balance between long-term health or environmental goals and short-term pleasure and hedonistic rewards (Réquillart et Soler, 2014). In other words, the difficulties in complying with new food-based guidelines are likely due to the lack of compatibility of consumers' preferences with the diets that they would have to adopt in order to comply with these guidelines.

An important issue is then to determine sustainable diets complying with health and environmental recommendations and compatible, as much as possible, with consumer preferences. In other words, the challenge is to identify dietary recommendations with the potential to improve health and environment but generating the smallest "taste costs" for the consumers.

A first group of methods to address this issue builds on linear programming (LP) models which are used to estimate least-cost diets complying with a list of dietary requirements (Henson, 1991; Conforti and d'Amicis, 2000). Such LP models have been recently used by nutritionists to determine optimal diets complying with nutritional or environmental recommendations (Darmon et al., 2006; Maillot et al., 2010; Macdiarmid et al., 2012; Darmon et al., 2002, 2003; Srinivasan et al., 2006; Shankar et al., 2008; Arnoult et al., 2010). These methods suffer from important shortcomings because the objective functions and the substitution possibilities among goods are always arbitrarily restricted, and not based on real consumers' preferences. Therefore they cannot really take into account the consumers' taste costs and then be used to infer how nutritional and environmental dietary norms might influence real-world consumers.

A second type of approach with a stronger theoretical basis uses empirically-estimated demand systems (see Thow et al. 2010, Etilé, 2011, and Eyles et al., 2012 for recent reviews). These studies typically estimate

price elasticities from demand curves, which are conceptually derived from constrained utility maximization, given prices and a budget constraint. This kind of research has been based on complete food demand systems (Smed et al., 2007, Allais et al. 2010; Briggs et al., 2013; Caillavet et al., 2014), which allows consideration of a large set of interdependent demand relationships. Such methods can support the simulation of impacts of price policies, taxes or subsidies, on food consumption and nutrient intakes. However, compliance with food-based or nutrient-based recommendations can only be assessed *ex-post* rather than introduced as constraints in order to determine the price modifications needed to comply with these constraints.

To overcome these limits, Irz et al. (2015) have developed a new analytical framework which builds on the microeconomic theory of the consumer under rationing, with the goal of identifying diets compatible with both dietary recommendations and consumer preferences. This framework is built to estimate the substitutions, and overall changes in diet, that would take place if consumers complied with these recommendations. Such a framework is used to assess the difficulty of achieving a given norm by identifying the magnitude and nature of the required substitutions in consumption. It also provides the basis for measuring the "taste cost" of complying with a particular nutritional dietary norm, which can then be used in conventional cost-benefit analysis. Compared to the demand system analyses used to assess the effect of price variations on consumption and nutrient intakes (and then finally, on compliance with nutritional or environmental recommendations), this method considers the dual problem which consists of determining the price system and the compensation value (i.e. the taste cost) such that a dietary recommendation can be adopted without loss of utility.

In the present paper, we use this theoretical framework to empirically estimate the health, environmental and welfare impacts of the adoption of various dietary guidelines by consumers. More precisely, we consider a set of nutrient-based (salt, SFA) and food-based (F&V, meat) dietary recommendations, determine the substitutions within the consumers' diet induced by their adoption, and estimate the loss of welfare (taste costs) induced by these changes. To deal with the health issue, we match the economic model with an epidemiological one, and assess the health impacts of diet changes in terms of chronic diseases prevalence and mortality. Similarly, to deal with the environmental issue, we estimate the effects of the diet changes on environmental indicators. By confronting the consumers' taste costs and the health and environmental outputs, we finally proceed a cost-benefit analysis of dietary recommendations.

In first section, we briefly present the theoretical model. In section 2, we present the data and the empirical methods used to simulate the impact of various dietary recommendations on diets, welfare, environment and health. In section 3, we present the empirical results for e set of food-based and nutrient-based recommendations. Section 4 concludes the paper.

2. The Behavioural Model

The main building block of the analysis is a model of dietary adjustment under nutritional and/or environmental constraints (henceforth simply referred to as "dietary constraints"), which was first proposed to investigate the economics of nutritional recommendations by Irz et al. (2015). Making the assumption that the environmental impact of food consumption is linear in the quantities consumed, as is implicit in Life Cycle Analysis (Ekvall et al., 2007), extension of the model to the environment sphere is methodologically straightforward. Formally, we adopt the conventional framework of neoclassical consumer theory by assuming that an individual chooses the consumption of *H* goods in quantities

$x=(x_1,...x_H)$ to maximize a strictly increasing, strictly quasi-concave, twice differentiable utility function $U(x_1,...x_H)$, subject to a linear budget constraint $p.x \leq M$, where p is a price vector and M denotes income. However, departing from the standard model, we now assume that the consumer operates under N additional linear constraints. Those constraints could, for instance, correspond to a maximum permissible CO_2 equivalent from the diet, a maximum consumption of meat, or, in the nutrition domain, maximum levels of consumption of "unhealthy" foods or nutrients (e.g. salt, saturated fat). Denoting by a_i^n the constant nutritional or environmental coefficient (henceforth referred to as technical coefficient) for any food i and target n, the value of which is known from LCA databases or food composition tables, the dietary constraints are expressed by:

$$\sum_{i=1}^{H} a_i^n x_i \leq r_n \ \forall n = 1,..., N \tag{1}$$

Solving the Hicksian Problem - The utility maximization problem under budget constraint and multiple linear constraints (1) is difficult to solve directly so that, following Jackson (1991), we first focus on its Hicksian counterpart. We denote the compensated (Hicksian) demand functions of the non-constrained problem by $h_i(p,U)$, and those of the constrained model by $\tilde{h}_i(p,U,A,r)$, where A is the *(N x H)* matrix of technical coefficients, and r the *N*-vector of maximum levels of the constraints. We then introduce the notion of shadow prices $\tilde{p}$, defined as the prices that would have to prevail for the unconstrained individual to choose the same bundle of goods as the constrained individual: $\tilde{h}_i(p,U,A,r) = h_i(\tilde{p},U)$. As shown in Jackson (1991) and Irz et al. (2015), those shadow prices are solutions of the following non-linear system:

$$\tilde{p}_i = p_i - \sum_{n=1}^{N} \mu_n a_{ni} \qquad i = 1,..., H$$

$$\sum_{i=1}^{H} a_i^n h_i(\tilde{P},U) = r_n \qquad n = 1,..., N < H \tag{2a \& 2b}$$

where $\mu \geq 0$ is the *N*-vector of Lagrange multipliers associated with the *N* dietary constraints in the expenditure minimization problem, and $\tilde{P}$ is the *H*-vector of shadow prices. The first set of equations (2a) is easily interpreted: each shadow price is the sum of the actual price and a sum of terms depending on the nutritional/environmental coefficients of each food, as well as the influence of each constraint on minimum expenditure as measured by the Lagrange multipliers. In general, system (2) is highly non-linear and cannot be solved analytically, but we circumvent that problem by deriving relevant static comparative results describing, at the margin, the relationship between food demand and dietary constraints. In the case of *N*-linear constraints, this requires the introduction of some notations. We first partition the *NxH* matrix of environmental and nutritional coefficients *A* into a square matrix *B* and a residual matrix *C* as follows:

$$A = \begin{pmatrix} a_{11} & \cdots & a_{1H} \\ \vdots & \ddots & \vdots \\ a_{N1} & \cdots & a_{NH} \end{pmatrix} = (BC), \text{where } B = \begin{pmatrix} a_{11} & \cdots & a_{1N} \\ \vdots & \ddots & \vdots \\ a_{N1} & \cdots & a_{NN} \end{pmatrix} \text{ and } C = \begin{pmatrix} a_{1N+1} & \cdots & a_{1H} \\ \vdots & \ddots & \vdots \\ a_{NN+1} & \cdots & a_{NH} \end{pmatrix}$$

Irz et al. (2015) derive an expression showing the change in the vector of shadow prices resulting from a marginal change in the constraint levels r:

$$\frac{\partial \tilde{P}}{\partial r} = \begin{pmatrix} \left[A.S. \begin{pmatrix} I_N \\ C'.(B')^{-1} \end{pmatrix} \right]^{-1} \\ C'.(B')^{-1}. \left[A.S. \begin{pmatrix} I_N \\ C'.(B')^{-1} \end{pmatrix} \right]^{-1} \end{pmatrix} \qquad (3)$$

where I_N denotes the NxN identity matrix, and S is the familiar HxH matrix of Slutsky coefficients (i.e., $s_{ij} = \partial h_i / \partial p_j$). The corresponding adjustments in Hicksian demands resulting from the same marginal change in the levels of the constraints follow immediately:

$$\frac{\partial \tilde{h}}{\partial r} = \frac{\partial h}{\partial \tilde{P}} \frac{\partial \tilde{P}}{\partial r} = S. \frac{\partial \tilde{P}}{\partial r} \qquad (4)$$

Expressions (3) and (4) fully characterize the dietary adjustments, in an Hicksian framework, as a function of two sets of parameters only: first, the Slutsky matrix S describes consumer preferences and measures the relative ease or difficulty of substituting foods for one another; and, second, matrix A gathers technical coefficients expressing the properties of each food in the nutritional and environmental domains. Given that the Slutsky matrix is typically estimated empirically from observations on actual purchase behaviours, we claim that the model is therefore based on realistic food preferences, unlike virtually all programming-based models of diet optimization that make arbitrary assumptions about food preferences, either explicitly (i.e, by imposing "palatability constraints") or implicitly (through the choice of an arbitrary objective function).

More generally, expressions (3) and (4) show that a change in the nutritional constraints has an impact on the entire diet. This is true even for the goods that do not enter the constraints directly, as long as they entertain some relationship of substitutability or complementarity with any of the goods entering the constraints (i.e., as long as at least one Slutsky term s_{ki} is different from zero). Further, the model indicates that the magnitude and sign of any change in demand for any given product is unknown *a-priori* but depends in a complex way on the product's technical coefficients and its substitutability with other products entering the constraints.

From an empirical perspective, what is important is that equations (3-4) can easily be calculated by combining a matrix of Hicksian demand parameters to a set of easily available technical coefficients. Hence, assuming that we have a matrix of price elasticities describing the behaviour of an unconstrained individual, equations (3-4) provide a means of inferring how that individual would modify his diet in order to comply with the imposition of dietary norms at the margin (e.g., how his/her consumption of any food would respond to, for instance, a reduction in the maximum permissible level of CO_2 equivalent emanating from his/her diet).

From Hicksian solution to Marshallian solution - The Hicksian problem solved above is a useful theoretical construct but real-world consumers operate under a budget constraint rather than a utility constraint, and policy simulations of the effects of dietary recommendations therefore require calculation of the associated

Marshallian solution. In pursuit of that goal, we first calculate the short-run private welfare cost[1] of satisfying the constraints as measured by the compensating variation *CV*. By definition, the compensating variation is the difference between the initial expenditure (more generally the initial wealth) and the expenditure that maintains the utility constant in the nutritionally-constrained problem. Note that in the constrained problem, final expenditure is evaluated at market prices (as prices do not change). The compensating variation is thus also a measure of the taste cost of the constraints. We have $CV = C(p,U) - \tilde{C}(p,U,A,r)$, where the two *C(.)* functions denote the minimum expenditure functions of the unconstrained and constrained problems respectively. Irz et al. (2015) show that the *CV* is calculated for any change in any of the constraint levels r_j as:

$$CV = -\sum_{i=1}^{H} p_i \frac{\partial \tilde{h}_i}{\partial r_j} \qquad (5)$$

Clearly, since the constrained solutions $\tilde{h}$ belong to the choice set of the unconstrained problems, $p.\tilde{h} \geq p.h$, and the *CV* is always negative. In absolute value, it represents the increase in the food budget necessary to maintain utility constant when the dietary constraints are imposed, or in other words the level of the compensation that would make the consumer indifferent between his original diet and the diet satisfying the constraints. It follows that an approximate solution to the change in Marshallian demand Δx can be calculated from the change in Hicksian demand Δh and the income effect associated with the removal of the compensation:

$$\Delta x - \Delta h = \tilde{h}.\varepsilon^R \frac{CV}{p.\tilde{h}} \qquad (6)$$

In this expression, ε^R denotes the vector of income (or expenditure) elasticities, which is empirically estimable, while the ratio $CV / p.\tilde{h}$ measures the negative percentage change in the food budget corresponding to the removal of the compensation. All the other terms are either observed (prices, consumption levels) or calculated from equations (3), (4) and (5).

3. The Empirical model

The behavioural model presented in the previous section is applied to estimate the variation in household consumption induced by the adoption of health-based and environmentally-based dietary recommendations for different representative households of the French population. In a second step, this variation in household consumption is translated into changes in individual food and nutrient intakes. The health effects are then assessed by using the epidemiologic DIETRON model, which permits estimation of the changes in mortality attributable to a change in diet in a given population. On the environmental side, changes in diets are converted into changes in environmental indicators using appropriate LCA-based technical coefficients. Finally, the effects of the recommendations on health, private welfare, and the environment are brought together in the analysis of the relative cost-effectiveness of different recommendations. As the model calibration was presented in detail in Irz et al. (2015), we summarize

---

[1] This welfare measure is "short-run" because it ignores the long-run health effects, and it is "private" because it ignores the external environmental cost. Those effects are taken into account in the empirical analysis, in which we calculate the cost-effectiveness of the recommendations.

below the empirical procedure rather concisely, insisting mainly on the new elements of the analysis related to the choice of constraints, the introduction of the environmental constraints, as well as the welfare assessment integrating environmental externalities.

Choice of Recommendations - The choice of dietary constraints to be analysed is based on commonly formulated recommendations justified on health and/or environmental grounds, as well as previous analyses of the sustainability properties of diets. An overarching objective is to assess whether synergies or trade-offs exist between the two sustainability dimensions (e.g., can recommendations promoting healthier diets be expected to also generate environmental benefits, and vice versa?). We first select three healthy diet recommendations because of their well-established potential to improve public health:

- Promotion of fruits and vegetables has been actively pursued in many countries, for instance through social marketing campaigns of the "five-a-day" type (Capacci and Mazzocchi, 2011; Silva et al., 2013).
- Reduction in salt intake is a common aim of public health nutrition campaigns (Shankar et al., 2013).
- Reduction in saturated fat intake remains at the core of most healthy diet recommendations (WHO, 2003).

In addition, the analysis of nutritional recommendations of Irz et al. (2015) concluded that targeting those three food groups or nutrients was the most cost-effective strategy (they¨examined altogether ten health-based recommendations).

On the environmental side, the climate change issue currently dominates the debate about food consumption (Macdiarmid et al., 2012) and we therefore select a constraint on the CO_2 equivalent of the diet, which is a summary measure describing how much global warming can be expected from consumption of that diet. Translating a reduction in greenhouse gas emissions into food-based recommendations usually results in prescriptions to reduce consumption of meat, most notably from ruminants. We therefore consider two related scenarios in the empirical analysis (namely, all meat and red meat). Altogether, this gives us a total of six recommendations to be examined empirically

Initial diet and behavioural parameters - The behavioural model is calibrated using KANTAR Worldpanel data from a panel of 19,000 representative consumers of the French population. Food consumption is aggregated into 22 categories, which are defined on pages 2-3 of the supplementary material of Allais et al. (2010) and are largely self-explanatory. The behavioural parameters necessary to estimate the model, namely a full set of price and expenditure elasticities corresponding to those 22 aggregates, are also drawn from Allais et al. (2010)[2] for four representative types of households differentiated according to income quartiles and henceforth referred to as "Modest", "Lower average", "Upper average", and "Well-off".

Technical coefficients of the food aggregates - The nutrient contents of the 22 food aggregates, which are needed to formulate the health constraints and simulate health effects, are calculated by combining the food composition database of the French dietary intake survey INCA2[3] and average adult intakes of the component foods of each aggregate drawn from INCA2. They have already been published as Table A.1 in Irz et al. (2015). On the environmental side, an environmental consulting firm, Greenext Service, assigned

---

[2] See http://ajae.oxfordjournals.org/content/suppl/2010/01/23/aap004.DC1/aap004supp.pdf. The price elasticities for the four income groups are reported in Tables 7-10 of that document and the expenditure elasticities in Table 6.
[3] INCA2 stands for "Étude Individuelle Nationale des Consommations Alimentaires 2006-7".

values to 391 foods for two environmental impact indicators: GHG emissions expressed in grams of carbon dioxide equivalent units, and air acidification (emissions in the atmosphere responsible for acid rains) in grams of sulfur dioxide equivalent units. The two indicators were assessed by life cycle analysis, defined as follows by the ISO14040 and 14044 standards: the "compilation and evaluation of the inputs, outputs and the potential environmental impacts of a product system throughout its life cycle" (ISO, 2006a and 2006b). Thus, the estimates of environmental impacts include the results associated with each stage of the production, transformation, packaging, distribution, use, and end-of-life of food products. Using a top-down approach combining French trade and production data and standard life cycle inventory data (Althaus et al., 2007), the final values for the two indicators reflected the average food product consumed in the French market (Greenext, 2012).

Simulation procedure for the behavioural model - We simulate the impact of a marginal change in the levels of the dietary constraints on Marshallian demands by applying an iterative procedure based on equations (3) to (5):

1- Given a 5% exogenous change *Δr* in the level of the constraints, we calculate the resulting changes in Hicksian demands through (3-4).
2- The quantities thus obtained and original prices are then combined to calculate the compensating variation (5) linked to the imposition of the change in constraint levels.
3- This compensation, which hypothetically would allow the consumer to maintain his utility level, is then removed to calculate the corresponding changes in Marshallian demands through (6). However, because the constraints are directly imposed on the Hicksian demands rather than Marshallian demands, there is no guarantee that the diets calculated in step 3 comply with the original set of constraints. The search for the solution therefore proceeds as follows.
4- Calculation of the level of the targeted food/nutrient/environmental indicator resulting from the Marshallian demands in step 3. If this Marshallian solution satisfies the constraints, it is kept as the final solution of our problem.
5- If the Marshallian solution does not satisfy the recommendation, we go back to the first step by adjusting the level of the starting constraints.

This iterative process ends when the Marshallian solution calculated in step 3 satisfies the constraints (as calculated in step 4).

Health and environmental impacts - Simulation of health effects first requires that changes in food consumption at household level, as described by the behavioural model, be translated into changes in individual intakes, distinguishing between males and females[4]. This is accomplished under the assumption that (i) the percentage changes in intakes are the same for all the members of a given household, and (ii) the percentage changes are the same for at-home and out-of-home consumption[5], and using the INCA2 dietary intake database. Changes in food intakes are converted into changes in nutrients using the

---

[4] Hence, the health model considers 8 types of individuals (i.e. 4 income groups * 2 genders).
[5] The dietary intake database covers all the foods consumed by an individual whereas the Kantar database only covers at-home consumption.

nutritional coefficients of the 22 aggregates, and those are then translated into changes in mortality due to diet-related chronic diseases by using the DIETRON epidemiological model of Scarborough et al. (2012)[6].

The parameters of the DIETRON model are derived from world-wide meta-analyses of dietary risk factors and are not country specific, so that adapting the DIETRON model to France only requires calibration of the initial mortality levels, by relevant causes. This is achieved by using the INSERM data on mortality in France attributable to major diet-related diseases. We limit the study to individuals between the age of 25 and 74 and therefore focus on the effects of dietary changes on premature deaths (i.e., occurring before the age of 75). The baseline numbers of deaths according to each disease and each income class are published in Table 3 of Irz et al. (2015), which shows that the diseases considered in DIETRON account for slightly more than one third of total French mortality.

The environmental indicators are calculated by applying the previously mentioned constant LCA-based coefficients for each food to measured or simulated dietary intakes. The results are presented in Table 1 for the initial (observed) average French diet across different gender and income groups. The calculated levels of CO2 eq. from the diet are consistent with the population average of 4092g/day reported by Vieux et al. (2012). For both pollutants and each income group, men are responsible for more emissions than women, which we explain by their larger energy intakes. There is a slight socio-economic gradient for GHGEs, with a positive association with income, which is not observed for SO2 eq.

[Table 1 here]

Cost-effectiveness analysis - Our model calculates the effects of dietary adjustments under an "as if" assumption, i.e. assuming that the consumer complies with the 5% change in the constraint level(s). In practice, however, behavioural change is difficult and requires public investment in social marketing campaigns and other types of interventions, with uncertain effectiveness. For this reason, our welfare assessment of alternative recommendations shies away from attempting to measure the cost of ensuring compliance with a given recommendation/constraint, but instead investigates a different question: what is the maximum amount that could be invested to promote a given recommendation so that the outcome would remain socially desirable (i.e., would increase social welfare)?

Promotion of a given set of recommendations generates benefits, in terms of improved health of the population (denoted B_h) and reduced environmental externalities (denoted B_e), as well as costs both to individuals (i.e., the taste cost as measured by -*CV* and capturing a loss of hedonic rewards) and the public sector (i.e, cost of interventions such as social marketing campaigns, denoted C_p). The cost effectiveness threshold of each recommendation is hence calculated as $C_p = B_e + B_h + CV$ [7], giving us a means of comparing the relative efficiency of all the selected recommendations.

The health benefit is quantified by applying a monetary value to the reduced mortality figures calculated by DIETRON. The value of a statistical life (VSL), which is interpreted as the effort, in terms of the resources used, that society is willing to make in order to reduce the risk of death, has been reviewed elsewhere (Treich, 2015), and its estimates vary substantially across countries and policy domains. For instance, in the

---

[6] More precisely, the dietary input data for the health model are intakes of: total energy (MJ/day); fruit (g/day); vegetables (g/day); fibers (g/day); total fat (% total energy); mono unsaturated fatty acids (% total energy); polyunsaturated fatty acids (% total energy); saturated fatty acids (% total energy); dietary cholesterol (% total energy); salt (g/day) (Scarborough, Allender et al., 2012).

[7] As previously mentioned, CV is negative.

transportation area, the VSL reported by Anderson et al. (2011) range from 1.8 million USD 2005 for New-Zealand to 3.3 million USD 2005 for the United States, with the three represented EU countries using values in the order of 2 million USD 2005. Alternatively, Irz et al. (2015) monetise lives saved on the basis of the cost threshold of a Quality Adjusted Life Year (QALY) that is applied in the UK to investigate the cost-effectiveness of medical care (e.g., drugs, procedures). This threshold is then applied to the average number of years of life saved for a death avoided (DA) in DIETRON, which gives a value ranging from €240k to €360k. Given the continuing debate related to the correct value of a statistical life (Doucouliagos et al., 2012), as well as widely varying values of a QALY used by different government departments in a given country[8], our baseline cost-effectiveness analysis relies on the most conservative assumption (€240/DA). The benefit estimates and cost-effectiveness threshold derived with this value should therefore be interpreted as absolute lower bounds. However, we complete the analysis by estimating benefits using the value of a death avoided more compatible with the VSL commonly used in decision making in the transport sector, namely €1 million.

On the environmental side, valuing the benefit of reduced externalities presents its own set of challenges. Regarding climate change, the European Union has initiated the world's largest carbon market, the Emission Trading Scheme (ETS), but it is widely regarded as dysfunctional (Stratham, 2013). The carbon price on that market peaked at €30/ton in 2008 but has shrunk as low as €4/ton in recent years, with this low price reflecting political failure and associated over-allocation of permits rather than the real value of carbon (Drew, 2008). In addition, some of the values used in policy assessment may ignore the biggest risks associated with climate change, and downplay the impact of current emissions on future generations. Ackerman and Stanton (2012) claim that, in a US context, inclusion of those considerations would boost the price of carbon from the widely used value of \$21/ton to \$900/ton. In the face of so much uncertainty, we rely on the meta-analysis of the social cost of carbon developed by Tol (2012). That author, after fitting a distribution of 232 published estimates, derives a median of €32/ton, a value which we adopt in our baseline analysis due to its rigour and objectivity. However, our sensitivity analysis also uses the value of 95-percentile of the distribution fitted by Tol (2012), which is equal to €185/t[9].

In the case of SO2, there is no market for emissions within the EU and the literature measuring shadow prices is dominated by US studies. Hence, of the twelve shadow prices reported by Dang and Mourougane (2014, Table 1), only one originates from an EU country (Germany, in 1995) and none from France, while the range of reported estimates is extremely large. One of the most rigorous and recent studies for the US is Mekaroonreung and Johnson (2012), who show how shadow prices depend on the choice of estimation method, and conclude to the superiority of non-deterministic methods on the basis of the compatibility of the estimated shadow prices with observed market prices. The preferred method results in shadow prices lying between 201 and 343\$/ton, which translates into a range of 176 to 300€/ton. We use the mid-point of this bracket (€238/t) in our welfare assessment.

4. Results

---

[8] Wolff and Orr (2009, p. 10) report for the UK QALY values ranging from £30k to £80k across government departments.
[9] We note that this high value is of the same order of magnitude as the highest tax currently implemented in the world (namely, 168USD/t in Sweden, which is equivalent to €148/t – see World Bank's background notes on the carbon tax available online at: http://www.worldbank.org/content/dam/Worldbank/document/SDN/background-note_carbon-tax.pdf).

The methodology is applied to simulate the effect on food consumption, nutrient intake, health, environment, short-run welfare and cost effectiveness of six different dietary constraints. In each case, the relative variation in the level of the constraint is five percent of its baseline level, and the direction is chosen so as to increase dietary quality (i.e., to reduce the maximum permissible level of relatively unhealthy nutrients/foods and increase the minimum permissible level of relatively healthy ones) or to lower the environmental footprint of food consumption.

Dietary adjustments and their impact on short-run welfare - We start with the impact of the different recommendations on food consumption, focusing on the "lower average" income group of households (Table 2). The decision to focus on this income group to report the first set of results is largely arbitrary, but the main results reported below are not dependent on that choice, and the corresponding results for the other three household types are presented in Appendix A, Tables A.1-A.3. Each column of Table 2 corresponds to a different constraint and presents two sets of percentages: the baseline contribution of each food group to the constrained quantity (i.e., food/nutrient/CO2eq) on the left, and the change in consumption resulting from the imposition of the constraint on the right. For the food-based constraints, it follows by construction that most of the baseline level of the constraint is accounted for by a narrow range of food products, even if we note that 6% of meat consumption originates from ready meals. By contrast, in the case of some nutrients such as sodium or in the case of the CO2 constraint, the contributions of the different food groups to the baseline level of the constraint are much more spread out in product space.

Turning to the results of the simulations, and focusing on the 'all meats' constraint, let us note at the outset that a five percent decrease in meat consumption corresponds to a daily consumption decrease of about 8 g/day. As shown in Table 2, imposition of this small variation in the constraint level results in relatively important changes in consumption of several food aggregates: the decrease in meat consumption is associated with a decrease in consumption of starchy foods (-2.2%) whereas consumption of dairy products increases (+3.4%).[10] Hence, the relations of complementarity and substitutability among food products captured by the model appear quantitatively important, which already suggests that simulating the health and environmental effects of dietary recommendation under a "ceteris paribus" assumption (i.e., assuming here constancy of the diet except for the decreased consumption of meat) would be inappropriate.

Considering the simulation results at a higher level of product disaggregation in Table 2, we note that some complex substitutions also occur within product groups. For instance, within the F&V group, the all meat constraint induces an increase in fresh fruit consumption as well as dry fruits consumption whereas the consumption of other products (processed fruits, F&V juices, and vegetables) decreases. Among animal products, fish consumption (7.5%) increases which could be expected but more surprisingly egg consumption (-3.3%) decreases. Consumption of the different categories of dairy products also increases.

[Table 2 here]

The consumption changes associated with the imposition of the other constraints are rather varied and difficult to summarise. However, for food-based constraints the results indicate that, compared to the simulated effect described above with regard to the all meat constraint, imposition of the constraint on red meat results in smaller adjustments in food consumption. This is understandable as this constraint is less

---

[10] Note that the decrease in consumption of the 'all meats' category is different from 5% (the target for an increase in the total consumption of meats). This is because the ready meals category also includes some meat. Then, the change in meat consumption takes into account the changes in consumption of the meat food category as well as the changes in the consumption of the other food categories which contain some meat.

demanding in the sense that it concerns a smaller fraction of the diet and substitution with other meats occurs leading to a small decrease in 'all meats' consumption (-0.7%). As compared to the constraint on all meats, the impact of this constraint on the other groups of food is of lower magnitude but in the same direction. In the contrary, imposing an increase in F&V consumption leads to important changes in the diet. In particular consumption of starchy products (-16%) and salt-fat products (-21%) are strongly affected.

The results relative to the nutrient-based or environment-based constraints are also heterogenous. In particular, the constraint imposed on CO2 leads to large changes in the diet. Changes at food group level are generally large (e.g all meats (-8%), starchy food (-12%), F&V (+9%), dairy products (-5%)) and at the product category level they are even larger. Consumption of animal products are negatively affected whereas F&V consumption is favored as well as the consumption of relatively energy dense foods such as salt-fat products or beverages. On the whole the consumer decreases consumption of products with a 'high' CO2 impact and increases the consumption of products with a 'low' CO2 impact. Surprisingly given that those products have a rather low CO2 impact, the consumption of starchy products decreases. This is the result in the model of complementarity and substitutability relationships among food products. Significant adjustments in consumption occur as a result of the imposition of the SFA constraint, which induces a reduction in consumption of dairy products and, at the same time, has differentiated impacts on the consumption of other animal products. Thus the consumption of red meat, cooked meat and eggs decreases whereas the consumption of other meats increases. In the case of the sodium constraint, the diet is significantly affected with a decrease in the consumption of the product categories that contribute most to salt intake (cooked meats, grains, cheeses, and salt-fat products).

Overall, the simulations reveal that compliance with diet recommendations by a rational consumer implies large changes in consumption patterns, whose economic, health and environmental effects can only be adequately assessed by considering adjustments in the whole diet. Those complex adjustments reflect the nature of consumers' preferences for foods and would not have been possible to anticipate at the outset.

To further understand how the model works, the percentage differences between shadow prices associated with each constraint and actual prices are given in Table 3 for the same "lower average" household type. Focusing on the 'all meats' constraint, we note that the shadow prices of all the food products containing meat are larger than actual prices in order to encourage lower consumption, as expected. However, the table also reveals that the relative differences between shadow and actual prices are larger for meat products (ranging from 9.8% to 13.3%) than for ready meals (3.3%). From the theory section, we know that, for a given consumer, the shadow price of a product is a function of: a) the cost of the constraint μ_n in equation (2a), which depends itself on substitution possibilities and other characteristics of food preferences; b) the meat content of the product; and c) its actual price. The difference between shadow and actual prices is then greater for meat products than for ready meals as their content in meat is low. In the case of a constraint on red meat consumption, the difference between shadow and actual prices is much lower than in the previous case. This is because the elasticity of demand for red meat demand is larger than that for all meats. In the case of red meat, there are relatively close substitutes (the other meats) whereas it is not the case for 'all meats'. It is thus easier for the consumer to reduce consumption of red meat than consumption of all meats. In the case of the F&V constraint, the relative difference between shadow and actual prices is negative as the constraint is designed to raise consumption. Moreover, its magnitude is quite large.

For the nutrient-based or CO2 recommendations, the shadow prices of most products differ from actual prices, simply indicating that those nutrients (or CO2) originate from a wide range of foods. For all these constraints, we observe that some of the differences are large (i.e., at least 20%) for several product categories, which suggests that part of the substitutions required to satisfy the constraint is relatively difficult. This is particularly the case for the CO2 recommendation as most differences are larger than 20% and can reach 80%, meaning that reducing the CO2 footprint of the diet is difficult.[11] The large differences between shadow and actual prices make intuitive sense: for instance, the constraint on saturated SFA implies a large shadow price of the oil group, and cheeses and butter, the sodium constraint is associated with a high shadow price of salt-fat products.

[Table 3 here]

The short-run welfare cost of satisfying the different constraints are measured by the compensating variations reported in the upper part of Table 4. The short-run welfare cost of satisfying the red meat constraint is the lowest (10 M€) whereas the largest is associated with the CO2 constraint (961 M€) followed by the constraint on F&V (466 M€). In relative term the short-run welfare costs are modest, as the cost of the CO2 constraint is only about 1.2% of the food budget. In most other cases, the relative welfare cost is smaller than half a percent of the food budget, and it is almost a negligible percentage for the constraints imposed on red meat and 'all meats'. However, before concluding to the insignificance of taste costs, one should keep in mind that the 5% variations in the levels of the constraints are also small – for instance, the decrease in 'all meats' consumption represents a decrease in consumption which is lower than 10 g per day. Further, the relative magnitudes of the CVs match the levels of dietary adjustments described in Table 2 and the differences between shadow and actual prices described in Table 3. Hence, the relatively large CV for the CO2 constraint is associated with large consumption changes and large differences between actual and shadow prices, while the opposite is true for the constraint imposed on red meat. Those CVs, which capture the hedonic or taste cost of healthier or more environmentally friendly diets, have to be weighed against the associated health and environmental effects for a full assessment.

[Table 4 here]

Effects on nutritional and environmental indicators - The analysis of health and environmental impacts starts by converting the consumption changes described in Table 2 into changes in nutrients and environmental indicators, as presented for the whole population in Table 5. Imposition of the constraints induces substantial adjustments in the nutritional profile of the diet, but the overall change in diet quality remains ambiguous. For instance, the F&V constraint induces desirable reductions in SFA, cholesterol, salt and energy intakes, but also an undesirable decrease in intake of fibers. Similar trade-offs in diet quality can be observed for all six constraints, which justifies pursuing the assessment of health impacts by applying DIETRON to translate those nutritional changes into unambiguous health outcomes (see next section).

The environmental impacts of the simulated dietary changes are characterized in Table 5 in terms of two indicators: greenhouse gas emissions (in equivalent CO2) and acidification (in equivalent SO2). With the exception of the SFA recommendation, all recommendations lead to a decrease in the environmental impact of the diet, and we also note that the relative reduction in SO2eq. is generally larger than that in

---

[11] At least when this reduction is interpreted as resulting from an implicit taxation scheme as implied by the methodology developed in the theory section.

CO2eq.[12] Hence, while our analysis reveals overall synergies between the pursuits of health and environmental goals (i.e., healthy eating recommendations tend to reduce the environmental footprint of food consumption), the results also indicate that those synergies do not occur systematically. Finally, as for the impact on nutrient intakes, the magnitudes of the changes in environmental indicators vary strongly across recommendations. In particular, recommendations on red meat or 'all meats' result in relatively small changes in environmental impacts, whereas the recommendations targeting F&V and CO2eq. generate larger environmental improvements.[13]

[Table 5 here]

Overall benefits and cost-effectiveness of the recommendations - We now bring together the economic, health, and environmental effects of the six recommendations. First, DIETRON is used to aggregate the complex nutritional adjustments previously discussed into a clear health outcome: the number of deaths avoided (DA) within the whole population due to the reduced incidence of CHD, strokes, and ten different types of cancer. Four constraints are estimated to save more than 2000 lives annually (Table 4). This represents in each case a three to four percent decrease in the total mortality attributable to the diseases included in the DIETRON model, which can be considered substantial given the relatively small changes that are imposed exogenously (i.e., 5% change in the constraint level). However, the two constraints on meat are also revealed to be relatively less effective in reducing mortality as they would save less than 250 lives annually, which is about ten times less than for the other four recommendations. Although the diet changes induced by these two recommendations targeting meat consumption are rather different, their overall impact on health is similar. Table 4 also presents the total environmental impacts of the dietary changes by reporting variations in the indicators of global warming (CO2 eq.) and acidification (SO2 eq.) for the whole population.

To compare the efficiency of the alternative recommendations, our analysis then proceeds in two steps. First, we define partial indicators of efficiency, which balance the consumer cost against the health or environmental impact as measured by a single indicator (Table 4). In a second step we present in Table 6 the global cost-effectiveness measure as explained in section 3.

The consumer cost per DA varies from €46k for red meat and sodium recommendations to €413 k for the CO2 recommendation. Those results indicate that the (partial) cost-effectiveness of the recommendations varies enormously, and that the most effective recommendations are not necessarily those that save the most lives. In the case of red meat, the high level of partial cost-effectiveness is attributable to the particularly small taste cost of the recommendation, which is understandable given the minor dietary adjustments and associated changes in shadow prices that we already documented for that constraint. In other words, the utility cost of reducing red meat consumption is minimal, so that even if that reduction produces relatively limited health gains, its partial cost-effectiveness is very high. The constraint on salt achieves the same level of partial cost-effectiveness but this is the result of both a significantly larger short-

---

[12] The exception is the recommendation on sodium.

[13] Of course, the latter occurs by construction. The reader should note that in Table 5, the composition of the diet in terms of SFA is expressed as a percentage of energy. Hence, the total change in SFA is the percentage reported in that row plus the percentage change in energy. In the case of the SFA constraint, this gives -2.3% -2.5%=-4.8%. This figure is not exactly equal to 5% because of: 1- the approximation used to calculate the Marshallian solution described in section 3 ("Simulation procedure etc"); and, 2- the conversion of consumption changes into intake changes (as explained in Section 3, "Health and environmental impacts"). In the case of the CO2 recommendation, we also note a small difference between the target (-5%) and the actual change (-5.3%).

run welfare cost and a larger impact on health. By contrast, on the basis of this partial analysis, promoting a recommendation to reduce GHGEs from food consumption is a very cost-ineffective way of reducing diet-related mortality. However, we also note that for all recommendations the cost per DA compares favourably with (i.e., is significantly smaller than) the VSL typically used in the evaluation of transportation projects (i.e., in excess of €1million).

Turning to environmental impacts, the consumer cost per kiloton of CO_2 avoided varies from €38 (red meat) to more than €300 (CO_2 eq.), except in the case of the recommendation targeting SFA, which has a negative environmental impact. When compared to the baseline estimate of the social cost of carbon discussed in the methodology section (32 €/t), only the recommendation on red meat appears to approach partial cost-effectiveness, although that recommendation results in a small absolute reduction in GHGEs. Even considering the high value for the price of carbon (i.e., the 95-percentile value of €185/t), the partial cost effectiveness of reducing GHGE by promoting dietary recommendations appears poor except for those recommendations targeting meat consumption. The results for SO_2 are even worse in terms of partial cost effectiveness: reducing SO_2eq. by one ton through dietary adjustment imposes a consumer cost varying from €1441 for the red meat constraint to more than €30000 for the salt constraint and even more than €100000 for the SFA constraint. Those values exceed all the reasonable estimates of the social cost of SO_2 emissions.

[Table 6 here]

However, a complete assessment of the cost-effectiveness of the various recommendations requires that the multiple benefits and costs of each measure be considered jointly. Those population-level benefits, private costs, as well as the cost-effectiveness threshold C_p that could be allocated to promote each recommendation while ensuring overall cost-effectiveness, are presented in Table 6. Given the difficulties in valuing health and environmental improvements discussed in section 3, the calculations are repeated in separate columns for different sets of parameters defined in the upper part of the table. For the lower bound of the value of a DA (€240k) and lower value of carbon (€32/t), the first column of results shows that it would be desirable to spend considerable annual amounts of resources to promote the recommendations targeting F&V (€193 million), salt (€554 million), SFA (€215 million) and red meat (€54 million) but not those targeting GHGEs and consumption of all meats. For the first four of those recommendations, we note that C_p vastly exceeds the typical cost of running a social marketing campaign to promote dietary change. For instance, with regard to healthy eating, the ex-post evaluation of Capacci and Mazzocchi (2011) found an 8% increase in F&V consumption following a three-year "five-a-day" campaign in the UK at a cost of less than £3 million (roughly €4million). Hence, even using extremely conservative parameters to value health benefits, and taking into account the taste cost of dietary adjustment typically ignored in public health analysis, our analysis indicates that the F&V, SFA, salt and red meat recommendations are likely to be highly cost-effective. If the benefit per DA is calculated from a value closer to the VSL (€1 million), or if we use a high price of carbon (€185/t), all six recommendations appear highly cost effective. Thus, in spite of the uncertainties surrounding the valuation of non-markets goods/bads, the analysis points to the social desirability of allocating more public resources to the promotion of sustainable diet recommendations.

Table 6 can also support decision making by establishing a reasonably clear ranking of the recommendations to be promoted. For all scenarios, the recommendation targeting salt achieves the highest level of cost effectiveness, followed by the F&V or SFA recommendation, depending on the choice

of valuation parameters. Hence, the three recommendations justified mainly on health grounds are more efficient than those with purely environmental (e.g., CO2 eq.) or mixed (e.g., red meat, all meats) objectives. This result is investigated further in table 7, which presents the breakdown of the total benefit into its health and environmental components. With the exception of the "all meat" recommendation monetized using the low value of a DA (€240k) and high value of CO2 (€185/t), the health benefit from adjustments in the diet always exceeds the environmental benefit. This is the case even though in absolute terms, the meat constraints, for instance, generate relatively small health benefits as measured by the total number of DAs in Table 4.

5. Conclusion

Ex-ante assessment of informational measures urging individuals to modify their food choices for health or environmental reasons requires a clear understanding of how whole diets might respond to these policies as foods are interrelated via complex relationships of substitutability and complementarity. In the present paper, we address this issue by proposing a whole-diet model to analyze changes in food choice when consumers are urged to comply with health and environmental dietary recommendations. This economic model, grounded in the theory of the consumer under rationing, is used to empirically estimate how the adjustments in one part of the diet, due to the adoption of such dietary recommendations, have potential consequences on the whole diet, and finally on health and environmental indicators.

This empirical analysis of a set of dietary recommendations contributes to the existing literature on sustainability of diets and the potential convergence of solutions to food-related health and environmental issues. However, in comparison with most of current approaches, our analysis takes a new step by explicitly taking into account consumers' preferences in the assessment of the effects of dietary recommendations. Indeed, unlike many other studies, the substitutions within the diet induced by the adoption of recommendations are endogenously defined on the basis of consumers' preferences expressed by price and expenditure elasticities.

The first contribution of this method is that it permits to calculate the 'taste' cost' incurred by consumers, that is, the loss of utility associated with the adoption of a dietary recommendation and hence the difficulty experienced by consumers to substitute goods for one another. This feature is essential to understand the full effect of sustainable diet recommendations on consumer welfare, health and the environment and hence bring some degree of realism to the analysis of sustainable diets. The second contribution of our approach is to convert the changes in diets induced by the adoption of dietary recommendations into health and environmental benefits. Thus, using an epidemiological model, on the one hand, and a dataset of environmental impacts of foods, on the other hand, it is possible to link the dietary changes simulated by the economic model to impacts on climate change and acidification indicators, and on premature mortality attributable to diet-related chronic diseases. The third contribution is to provide a framework for carrying out the benefit-cost analysis of dietary recommendations. That framework weighs the taste cost incurred by consumers against the health and environmental benefits induced by their adoption.

Our analysis also presents some limitations, some of which relate to the data used. Health parameters used in the epidemiological model, as well as GHGEs and acidification impacts of foods remain, to some extent, uncertain. The estimation of health and environmental impacts of dietary recommendations will have to be improved in the future as these data become more accurate. Another limitation is due to the fact that we

assessed the substitutions among food categories and nutrients on the basis of consumption data, but estimated diet quality changes from a database on individual intakes. To connect the two, we applied the percentage variations in consumption to the corresponding individual intake data. This procedure may have introduced some inaccuracies which are difficult to estimate (but also to avoid). Another limitation is due to the fact that we assumed that the consumer's utility was only a function of the quantities of the products consumed. Therefore we implicitly assumed that the consumer's utility and demand relationships were unaffected by health or environmental benefits. Even if we address this issue partially when valuing the health and environmental benefits gained from the policies, a more general framework linking explicitly nutritional and environmental recommendations to changes in consumers' preferences, and hence integrating other dimensions than price and quantity into the choice problem, remains to be elaborated. Lastly, there is an important limitation related to the consideration of time in the model. If it is admissible to assume that changes in diets generate environmental benefits as soon as they are implemented, it is not necessarily the case for health issues. Changes in diets must be implemented for some years to have significant impacts on health and nutritional status of individuals. It will then be necessary to better integrate a dynamic analysis of health issue in future research. Despite these limitations, we have demonstrated the practicality of the approach by investigating how food consumption, economic welfare, health and environmental outcomes would respond if French consumers adopted food-based, nutrient-based or environment-based recommendations.

The results confirm the need to consider the effects of food consumption recommendations, even if they concern only one component (sodium, SFA, CO_2) or one food category (F&V, meat), on the whole diet as, in most cases, they generate changes in the consumption of many food categories in a way that is difficult to predict. Looking solely at the magnitude of the environmental and health effects, a reduction in CO_2 content of diet as well as an increase in F&V consumption represent particularly attractive options for health and environment. Even if those measures result only in modest (5%) changes in consumption of the targeted quantity (F&V, CO_2), they are likely to (i) prevent in excess of 2100 deaths annually, and (ii) reduce the GHGEs by 1500 to 2900 kt of eq. CO_2 per year.

Regarding the partial cost-effectiveness analysis, the recommendation to reduce red meat consumption by 5% ranks highest for health and the two environmental indicators. The least partially cost-effective measure is the recommendation to reduce CO_2 emissions by 5% because, as it affects a large range of food groups, the consumers' costs are very high. The recommendation to increase by 5% the F&V consumption better balances costs and benefits. It is worthwhile to note that in most cases, the recommendations have positive impacts, even small, on both health and the environment, which confirms the possible synergies between the two domains. However, those synergies do not occur systematically, since the recommendation to decrease by 5% SFA leads to a large number of premature deaths avoided but to an increase in the carbon footprint of the diets.

Besides the ranking of different types of dietary recommendations, our analysis brings some additional insights for the formulation of healthy and environmentally-friendly eating policies. Hence, the large differences between shadow and actual prices that we estimated for the health-based (F&V, sodium, SFA) and CO_2 recommendations suggest that fiscal measures are unlikely to be very effective in improving dietary quality unless the tax or subsidy rates are substantial. Note however, that the gap between the shadow and actual prices is much lower for the recommendations promoting a decrease in all meats or red

meat consumption (and concentrated on only these food categories). This would suggest that price policies would be more relevant in this case.

To complete the cost-benefit analysis, we estimated the maximum amount that could be invested by public authorities to promote a given recommendation so that the outcome would remain socially desirable. To compute this maximum amount, we reviewed monetary values of a statistical life (VSL) and of a Quality Adjusted Life Year (QALY) in public health literature, and social costs of CO_2 and SO_2 in environmental literature. Considering a range of plausible values, it turns out that: (i) informational measures focused on F&V, SFA and sodium intakes, provided that they lead to at least a 5% change in the consumption of the targeted food or nutrients, would be valuable investments, given their impacts on health and/or environmental indicators; (ii) informational measures targeting CO_2, red meat or all meats consumption would be valuable investments only for high values of CO_2 market prices (much greater than currently observed), although that result is also sensitive to the valuation of DAs.

Finally, we show that the monetary values of health benefits induced by dietary recommendations are always much greater that those of environmental benefits. This suggests prioritizing health rather than environmental issues in information campaigns dealing with food consumption. The fact that environmental considerations have been taken into account in the formulation of dietary recommendations only very recently and partially does not appear problematic.

We conclude with a broad policy message. In recent years, the consensus about effective ways of promoting healthier and more sustainable diets has shifted, with increasing pessimism towards traditional informational measures, i.e. the formulation of dietary recommendations and their promotion via social marketing campaigns, labelling regulation and/or educational measures. Hence, Traill (2012) in his presidential address on the economics of nutrition policy evaluation concluded that "Evidence suggests that information measures (to perform or persuade) do not much change diets". This pessimism contrasts not only with the results of our analysis, but also the broader evidence that, at least on the health side, diet quality has in fact improved in most industrialised countries (Mazzocchi et al., 2007), even in a country such as the United States which is at the forefront of the "obesity epidemic" (Beatty et al., 2014). Further, when looking at broad trends over a long period of time, there is evidence of very large changes in dietary habits that, at least in some countries, are explained in part by the effect of public interventions.[14] While recognising the difficulty of identifying the causal determinants of those trends (e.g., price and income changes versus health considerations), what might be needed is: 1- A revision of expectations regarding the effect of a short term intervention. Our analysis suggest that even a minute change in food consumption patterns can ensure cost effectiveness of a policy; and 2- A more sustained effort in promoting sustainable diet recommendations. At that level, the analysis indicates that public expenditures in the tens or hundreds of millions of Euros per year – levels that are dwarfed by expenditure on food and drinks advertising by private businesses (Matthews, 2007) - may be justified on efficiency grounds.
