Abstract

We construct a model to predict how consumers will respond to better information about the carbon content of 42 foods and a nonfood composite as well as product categories through a label, and provide guidance as to what kinds of goods would provide the highest CO$_2$eq emission reductions through a labeling scheme. Our model assumes that consumers value their individual carbon footprint, allowing us to utilize estimates of own- and cross-price elasticities of demand from the literature on demand analysis. We make three different assumptions about how consumers currently value their carbon footprint and find that when a label informs consumers, their baseline perception matters. We also find that carbon labels on alcohol and meat would achieve the largest decreases in carbon emissions.

**Keywords:** Carbon emissions, food labeling

**JEL Classification:** Q53, D83, Q18
Introduction

Research suggests that minor adjustments to the mix and carbon content of consumer products may result in substantial carbon emission reductions (Dietz et al. 2009; Cohen and Vandenbergh 2012). While this research implies some changes to consumer behavior are politically feasible and would be acceptable to many consumers, rarely does this line of research employ demand analysis to calculate the consumer welfare impacts of these carbon mitigation behaviors or predict the likely substitutes for high carbon goods and services (e.g., Weber and Matthews 2008, Vanclay et al. 2011, EWG 2011). In this paper, we construct a model to predict how consumers will respond to better information about the carbon content of food products through a label, and we provide guidance as to the kinds of goods that would provide the highest emission reductions through a labeling scheme.

To our knowledge, this study is the first to apply a rigorous economic model to address the question of how consumers will respond to carbon labels. The evaluation of the impact of carbon labels on carbon emissions is addressed in the Life Cycle Assessment (LCA) literature, which typically presumes that a low-carbon good is a substitute for a high-carbon good (European Communities 2006, Bin and Dowlatabadi 2005, Jones and Kammen 2011). For example, chicken, which is produced with lower carbon emissions, is assumed to be a substitute for beef, which is produced with higher carbon emissions. However, chicken could be a substitute or a complement to many other foods as well. The responsiveness of demand for a product to changes in its own price and prices of complements and substitutes has been rigorously evaluated and quantified in the demand analysis literature (i.e., elasticities of demand). In particular, the cross-price elasticities of demand quantify these trade-offs between related goods, such as chicken and beef, and thus are a natural input into understanding consumer responsiveness to information on carbon footprints.

We develop a model that integrates elasticities of demand with LCA information on the carbon emissions of different products, and we apply this model to U.S. food products. We find that goods where consumers have a low carbon substitute, an inaccurate belief about the carbon footprint of the good, and where high carbon goods have a large market share are most likely to result in large reductions in carbon just from being labeled.

Background

The market for products with labels that include “sustainable,” “environmentally friendly” and “eco” have been increasing over time. In 2009, almost 7,000 products on U.S. shelves included some sort of environmental claim (Mintel Group 2011, quoted in Cohen and Vandenbergh 2012). These product labels lower the cost of information about the environmental attributes of goods, and thus may help consumers voluntarily reduce their carbon footprint. The prospects for adoption of a comprehensive international carbon tax or cap and trade system over the next
decade are slim, however, and public or private carbon labeling systems are emerging as a gap-filling measure in the interim (Vandenbergh et al. 2010). These systems can affect global supply chains prior to adoption of international or domestic carbon-pricing measures and can complement these measures after they are adopted.

Although carbon labels may be able to reduce carbon emissions from the production of consumer goods, they may have additional impacts, such as a rebound effect whereby consumers decrease other expenditures on environmental protection (Kotchen 2005, 2006), or a spillover effect where labels heighten awareness and cause consumers to increase their overall demand for environmental protection (Kals et al. 1999). The consumer response may be only half the story. Firms may reduce their carbon footprints for reasons beyond willingness to pay for carbon reductions, including boycott threats or more generalized reputational concerns, potential efficiency gains in supply chains, and other factors (Lenox and Eesley 2009, Baron and Diermeier 2007).

This paper assumes consumers are willing to pay to reduce their personal carbon footprints. This assumption is supported by evidence on the willingness to pay for various carbon mitigation programs (Akter and Bennett 2010, Lee et al. 2010, Carlsson et al. 2010, Cai et al. 2010, Johnson and Nemet 2010, Solomon and Johnston 2009, Viscusi and Zeckhauser 2006) and direct measures of mean willingness to pay for a 1-kg reduction in carbon dioxide that range between $8 and $32 (Diederich and Goeschl 2011, Loschel et al. 2010, MacKerron et al. 2009, Brouwer et al. 2008). One finding of these surveys is the existence of ‘fat tails’ for willingness to pay for reductions in carbon dioxide, and that the median is lower than mean values for climate change mitigation. While some respondents are willing to pay large amounts to reduce greenhouse gas emissions, a large mass of the distribution is willing to pay nothing or even negative amounts. This heterogeneity is a problem if it is correlated with food consumption. For instance, if individuals who consume relatively large quantities of beef and are relatively responsive to the change in price of beef are also not concerned about climate change or have a low willingness to pay for carbon reductions, then our model will overstate the gains to labeling beef. We acknowledge this shortcoming and propose that future studies estimate elasticities of demand for products of interest separately, depending on whether they have a high or low willingness to pay for personal carbon footprint reductions.2

Calculating the carbon footprint of an apple or potato is a non-trivial task. Different assumptions about production, transportation, and the carbon content of fuels used may result in wildly different estimates. Consumer post-purchase choices—the way

1 The mean willingness to pay for a 1-kilogram reduction in carbon dioxide emissions in these studies are originally reported in euros and we assumed 1 euro is worth $1.277 USD.
2 This could be accomplished using current data by using organic food purchases as a proxy for green sentiment.
a potato is cooked\textsuperscript{3}, how intensively a device is used, the source of electricity for a device, or whether material is recycled—can also change the carbon impact significantly. In response to the growing need for consistent emissions calculations and reporting of products, many ongoing efforts around the world are compiling databases of product emissions and impacts in a consistent manner. However, the focus of these standards is performance tracking of products over time, rather than product comparison, comparative assertions, or product labeling. Key issues remain unresolved, including the standards for manufacturer and supplier cooperation in data sharing, drawing an exact boundary for carbon assessment across companies, incorporating very uncertain land-use change related carbon, and for addressing the unknown life cycle paths of complex products such as consumer electronics produced in Southeast Asia (WRI/WBCSD, 2010).

This is not a paper on establishing carbon footprints, but rather an effort to integrate information on carbon footprints with consumer behavior. We use what we believe are the best, but not final, estimates of the carbon footprint of food products. Because of data limitations, we limit our analysis to broad categories of foods such as ‘citrus’ or ‘fish’. Figure 1 shows the level of analysis we use, and how it could be expanded into a hypothetical third stage of analysis. Broadly labeling products as ‘apples’ or even ‘fish’ misses major opportunities for carbon reductions, such as modeling substitutions between seasonal and off-season produce or very different carbon footprints within categories such as fresh lobster (19.60 kg CO\textsubscript{2}eq/kg) and fresh herring (1.34 kg CO\textsubscript{2}eq/kg), which in our analysis are lumped together as fish (8.86 kg CO\textsubscript{2}eq/kg).\textsuperscript{4} Fortunately, our model can be expanded when new information becomes available on product carbon footprints and the associated consumer elasticities of demand.

\textbf{The Economic Model}

We model the representative consumer’s willingness to reduce her personal carbon footprint as a disutility for personal carbon emissions. Without labels, the consumer may not know what her carbon emissions are but has a perceived footprint, $\tilde{E}$, which may not be the same as the actual footprint, $E$. Thus the consumer maximizes utility over goods $x_1$ through $x_n$ and $\tilde{E}$ subject to a budget constraint and an emissions constraint:

$$\text{max } U(x_1, x_2, \ldots, x_n, \tilde{E})$$

s. t.

$$M \geq x_1 P_1 + x_2 P_2 + \ldots + x_n P_n$$

$$\tilde{E} = x_1 \tilde{E}_1 + x_2 \tilde{E}_2 + \ldots + x_n \tilde{E}_n,$$

\textsuperscript{3} http://www.carbon-label.com/our-news/case-studies/tesco

\textsuperscript{4} ecoinvent v.2 database (Frischknecht et al. 2005; Swiss Center for Life Cycle Inventories 2012)
where \( P_n \) is the market price for product \( n \), and \( M \) is total expenditure on all market goods and services for the representative consumer. The actual emissions from each consumer is \( E \) and is based on the actual carbon footprint of each item, \( E = x_1 E_1 + x_2 E_2 + \ldots + x_n E_n \). We solve the consumer maximization problem by setting up a Lagrangian with two constraints:

\[
L = U(x_1, x_2, \ldots, x_n, E) + \lambda (M - x_1 P_1 - x_2 P_2 - \ldots - x_n P_n) + \xi (E - x_1 E_1 - x_2 E_2 - \ldots - x_n E_n).
\]

Taking the derivative of \( L \) with respect to \( x_1 \) through \( x_n \), and results in \( n + 1 \) first order conditions:

\[
\frac{\partial u}{\partial x_1} = \lambda P_1 + \xi E_1,
\]

\[
\vdots
\]

\[
\frac{\partial u}{\partial x_i} = \lambda P_i + \xi E_i,
\]

\[
\vdots
\]

\[
\frac{\partial u}{\partial x_n} = \lambda P_n + \xi E_n,
\]

\[
\frac{\partial u}{\partial E} = \xi,
\]

where \( \frac{\partial u}{\partial x_i} > 0, \frac{\partial^2 u}{\partial x_i^2} < 0 \ \forall \ i \) and \( \frac{\partial u}{\partial E} < 0 \), \( \lambda \) is the marginal utility of income and \( \xi \) is the marginal disutility of emissions. The shadow values \( \lambda \) and \( \xi \) can be combined to equal the value consumers’ place on personally reducing a unit of emissions, which we denote \( \psi = \xi / \lambda \). This parameter has been estimated from stated preference and experimental studies (Diederich and Goeschl 2011, Loschel et al. 2010, MacKerron et al. 2009, Brouwer et al. 2008). Using \( \psi \), we can rewrite the first-order conditions with the \( i \)th condition being:

\[
\frac{\partial u}{\partial x_i} = \lambda (P_i + \psi E_i).
\]

These conditions can be solved for demand functions that have as their argument \((P_1 + \psi E_1, P_2 + \psi E_2, \ldots P_n + \psi E_n)\). Thus instead of \( D_i(P_1, P_2, \ldots P_n, M) \), we can rewrite the demand for good \( i \) as:

\[
D_i(P_1 + \psi E_1, P_2 + \psi E_2, \ldots P_n + \psi E_n) = \tilde{D}_i(P_1, P_2, \ldots P_n, E_1, E_2, \ldots E_n).
\]

**Consumer Responses to Changes in Emissions**

Ultimately, we are interested in how the demand for a product will change with a change in perceived emissions due to carbon labels. The derivative of the demand function with respect to a change in the perceived emissions of good \( i \) will be:

\[
\frac{\partial D_i}{\partial E_i} = \left( \frac{\partial D_i}{\partial P_i} \right) \psi,
\]
where $\frac{\partial D_i}{\partial P_j}$ can be deduced from conventional estimates of elasticities of demand for product $i$. For example, the elasticity of demand for product $i$ with respect to price of $j$ is:

$$\eta_{Q_i,P_j} = \left(\frac{\partial D_i}{\partial P_j}\right) \left(\frac{P_j}{Q_i}\right),$$

which implies that the slope of demand for product $i$ with respect to price $j$ is:

$$\eta_{Q_i,P_j} \left(Q_i P_j\right) = \frac{\partial D_i}{\partial P_j}.$$

Hence, the elasticity of demand for product $i$ with respect to a change in perceived emissions in product $j$ is:

$$\eta_{Q_i,E_j} = \left(\frac{\partial D_i}{\partial E_j}\right) \left(\frac{E_j}{Q_i}\right) = \left(\frac{\partial D_i}{\partial P_j}\right) \psi \left(\frac{E_j}{Q_i}\right) = \left(\eta_{Q_i,P_j}\right) \psi \left(\frac{E_j}{Q_i}\right).$$

The elasticities of demand for products, $\eta_{Q_i,P_j}$, are parameters readily available in the demand analysis literature. Thus, we may use own- and cross-price elasticities of demand that have been previously estimated to predict which products consumers may be willing to substitute away from and between.

To understand what total emissions are, we can sum the product of each good and its actual emissions, $E_i$, such that:

$$E = E_1 \bar{D}_1(P_1, P_2, ... P_n, E_1, E_2, ... E_n) + E_2 \bar{D}_2(\cdot) + ... + E_n \bar{D}_n(\cdot).$$

A change in the perceived emissions of good $i$, $\bar{E}_i$, results in a change of the total emissions for the representative consumer that is equivalent to: j

$$\frac{\partial E}{\partial E_i} = E_i \left(\frac{\partial \bar{E}_i}{\partial \bar{E}_i}\right) + \sum_{j \neq i} E_j \left(\frac{\partial \bar{E}_j}{\partial \bar{E}_i}\right).$$

The first term on the left-hand side is the own-price effect, or how a consumer alters her purchasing decisions as a result of knowing more about a good’s carbon content. The second term is the impact of a change in perceived emissions on consumer choices for substitutes and complements. If we rearrange the order of goods such that the first $k$ goods are substitutes for $i$, and the last $n - k - 1$ goods are complements for $i$, we can rewrite this equation as:

$$\frac{\partial E}{\partial E_i} = E_i \left(\frac{\partial \bar{E}_i}{\partial \bar{E}_i}\right) + \sum_{j=1}^{k} E_j \left(\frac{\partial \bar{E}_j}{\partial \bar{E}_i}\right) + \sum_{j=k+1}^{n} E_j \left(\frac{\partial \bar{E}_j}{\partial \bar{E}_i}\right).$$

This can be rewritten as:
\[
\frac{\partial E}{\partial E_i} = E_i \psi \frac{\partial D_i}{\partial P_i} + \sum_{j=1}^{k} E_j \psi \frac{\partial D_j}{\partial P_i} + \sum_{j=k+1}^{n} E_j \psi \frac{\partial D_j}{\partial P_i}.
\]

If consumers value a reduction in their personal carbon emissions, then the first term will be negative, the second term will be positive, and the last term will be negative. For example, if a consumer learns that beef is much more carbon intensive than previously thought, she will reduce her beef consumption to decrease her carbon emissions; however, her personal emissions from substitutes for beef will increase and her personal emissions for complements for beef will decrease. The net effect is ambiguous, unless we know that the emissions from substitutes are small or emissions from complements are large. A good candidate for a carbon label would be one for which:

\[
\left| E_i \frac{\partial D_i}{\partial P_i} + \sum_{j=k+1}^{n} E_j \frac{\partial D_j}{\partial P_i} \right| \gg \left| \sum_{j=1}^{k} E_j \frac{\partial D_j}{\partial P_i} \right|.
\]

In other words, goods for which the own-price and complementary effects are greater in magnitude than the substitution effect.

The effects of a carbon label on emissions can be simulated using this model for any number of products. The only constraint on the number of products chosen to model these effects is the data necessary to parameterize the model, which include elasticities of demand, prices and quantities for products included in the analysis, and the retail-level carbon emissions from each product. In the next section, we discuss the parameterization of the model.

**Parameters for the Simulations Based on the Model**

We include 42 food products and a nonfood composite in our analysis. We use publicly available price and quantity data and elasticities of demand from the demand analysis literature, and we construct measures of carbon emissions for each product using data primarily from LCA databases such as CleanMetrics and ecoinvent, but supplemented with additional data from studies from the literature.

**Price Elasticities of Demand for Food Products**

Okrent and Alston (2012) estimated demand for 43 disaggregated products, using a two-stage budgeting framework (figure 1). For the first stage, they estimated demand for six food-at-home (FAH) product groups (cereals & bakery products, dairy, meat & eggs, fruits & vegetables, nonalcoholic beverages, and other FAH), a food-away-from-home (FAFH) and alcoholic beverages group, and a nonfood group. They then modeled the second-stage allocation of expenditures on the seven food groups as weakly separable groups, including: (i) flour & prepared flour mixes, breakfast cereals, rice & pasta, nonwhite bread, white bread, biscuits, rolls & muffins, cakes & cookies, and other bakery products, (ii) beef, pork, other red meat, poultry, fish & seafood, and eggs, (iii) milk, cheese, ice cream & frozen desserts, and
other dairy products, (iv) apples, bananas, citrus, other fresh fruits, potatoes, lettuce, tomatoes, other fresh vegetables, and processed fruits & vegetables, (v) frozen, noncarbonated juices & drinks, nonfrozen, noncarbonated juices & drinks, carbonated drinks, and coffee & tea, (vi) sugars & sweeteners, fats & oils, soups, frozen meals, snacks, spices, seasonings, condiments & sauces, and other miscellaneous foods, and (vii) full-service FAFH, limited-service FAFH, other FAFH, and alcoholic beverages. Using estimates of elasticities of demand from the first- and second-stage allocations, they approximated elasticities of demand conditional on total expenditure for all goods and services.

To estimate the first and second stages, Okrent and Alston (2012) used the Generalized Ordinary Differential Demand System (Eales et al. 1997) with expenditure and price data from the Bureau of Labor Statistics. First, using the 1998–2010 diary portion of the Consumer Expenditure Surveys, they constructed a monthly time series of household expenditures by aggregating detailed weekly expenditure data into 43 products (i.e., three FAFH products, 38 FAH products, alcoholic beverages, and a nonfood composite) and then averaged these data over households for a given month (Bureau of Labor Statistics 2010b). They then matched the average monthly expenditures to monthly consumer price indexes (Bureau of Labor Statistics 2010c).

Following Carpentier and Guyomard (2001), they approximated the unconditional elasticities using the first- and second-stage elasticities of demand to approximate the unconditional elasticities of demand. The superscript denotes the composite group and the subscript denotes the elementary good. The authors then approximated the unconditional Marshallian expenditure ($\eta_{iM}$) and price ($\eta_{ij}$) elasticities of demand as

$$\eta_{iM} \approx \eta_{iM}' \eta_{IM}',$$  \hspace{1cm} (1)

$$\eta_{ij} \approx \delta^{IJ} \eta_{ij}' + w_j^I \eta_{iM}' \eta_{ijM}' \left( \delta^{IJ} / \eta_{ijM}' + \eta_{IJ}' \right) + w_j^I w_j^M \eta_{iM}' \eta_{IJ}' \left( \eta_{ijM}' - 1 \right),$$ \hspace{1cm} (2)

where

$\eta_{iM}' = $ expenditure elasticity for good $i \in I$ conditional on expenditure for group $I$,

$\eta_{IM}' = $ expenditure elasticity for composite group $I$ with respect to total expenditure, $M$,

$\eta_{ij}' = $ Marshallian elasticity of demand for good $i \in I$ with respect to price $j \in J$ conditional on $I = J$,

$\eta_{IJ}' = $ Marshallian elasticity of demand for composite group $I$ with respect to composite price $J$.  

\(w_j' = \) budget share for good \(j \in J\) conditional on \(J\),

\(w' = \) budget share for composite group \(J\),

\(\delta_{ij} = \begin{cases} 1, & \text{if } I = J \\ 0, & \text{otherwise} \end{cases}\)

To date, the elasticities of demand estimated by Okrent and Alston (2012) are the most comprehensive set of elasticities for investigating the effects of a policy like carbon labeling on food consumption. They include a large number of foods at a level of disaggregation that allows us to simulate somewhat precisely the effects on demand and carbon emissions of a label that changes carbon perceptions. Comparable studies to Okrent and Alston (2012) do not have the level of disaggregation appropriate for the simulations. Also, most of the own-price elasticities are negative, which is consistent with demand theory, and statistically different from zero at the 10% level of significance.

**Prices and Quantities of Food and Nonfood Products**

The price data for the FAH products are based on several sources (Table 1). Most of the price data are from the Average Price Database (APD) published by U.S. Department of Labor, Bureau of Labor Statistics (2010a). The APD contains monthly national average prices for many basic FAH products that are used in the construction of the Consumer Price Indexes. We first use a simple average of the monthly prices for calendar year 2008 for the FAH products in the APD. We then constructed expenditure share-weighted average prices for many of the foods using the disaggregated prices in this database. For example, the price for poultry is the weighted average price per pound of (1) chicken, fresh, whole, (2) chicken breast, bone-in, (3) chicken legs, bone-in, (4) chicken breast, boneless, and (5) turkey, frozen, whole, with the expenditure shares for each poultry component as weights. The expenditure shares for each component disaggregated product are derived from the 2008 Consumer Expenditure Survey (U.S. Department of Labor, Bureau of Labor Statistics 2010b).

Because the APD does not cover all FAH products, we also used the Quarterly Food-at-Home Price Database (QFAHPD), which contains household expenditure-weighted prices for 52 food groups across 30 market areas (U.S. Department of Agriculture, Economic Research Service 2011). We calculated the price levels of FAH products using these data as a simple average across markets and quarters in 2008.

Quantities for the FAH products are derived as average annual household expenditures for a particular FAH product in 2008 (Column 2 in Table 2) divided by the average price per unit of measure (Column 1 of Table 2). The 2008 average annual household expenditures are derived from the 2008 Consumer Expenditure Survey public microdata (U.S. Department of Labor, Bureau of Labor Statistics 2010b). Most of the quantities are in pounds, except for carbonated beverages,
frozen drinks, eggs, and milk. To make these quantities compatible with the carbon footprint information, we convert them to kilograms in the simulation.

The prices of and quantities for FAFH and alcohol products are derived somewhat differently than the prices of and quantities for the FAH products. For these products, expenditures and quantities are available but prices are not. We calculated the prices of the FAFH and alcohol products as total annual household expenditures on FAFH products in 2008 using the Consumer Expenditure Survey public microdata (U.S. Department of Labor, Bureau of Labor Statistics 2010b) divided by the quantities of FAFH products consumed by households. The quantities of FAFH and alcohol products consumed are based on the 2007-08 National Health and Nutrition Examination Survey. In this survey, individuals are asked to recall the type, quantity, and source of foods they consumed in a 24-hour period. For example, average daily consumption of food from limited-service FAFH for an individual in 2007-08 was 198.53 grams (Table 2). We then converted individual daily consumption into household annual consumption by multiplying Column 1 in Table 2 by 365 days and the average household size in 2008, which was 2.5 persons. The price per pound is then annual household expenditures for each FAFH and alcohol product in 2008 divided by pounds of each product consumed by a household.

**Carbon Footprints Data**

The carbon footprint of any good is composed of emissions from various life cycle stages and is measured in kilograms of carbon dioxide equivalency (CO2eq) which includes other greenhouse gasses such as methane and nitrous oxide. The first stage is production. We use information primarily from the ecoinvent v.2 database (Swiss Center for Life Cycle Inventories), CleanMetrics (CleanMetrics 2011), Meat Eater’s Guide (Environmental Working Group 2011), and the Economic Input-Output Life Cycle Assessment (EIO LCA) Online database (Carnegie Mellon University Green Design Institute 2008). Additional information was obtained from SAI Platform (Mordini et al. 2009), Jungbluth (2005), and Coca-Cola Corporate Responsibility (Coca-Cola Enterprise, 2011). Most of these studies include raw material extraction and processing but ignore any indirect land use effects. The second stage is post-production, which generally consists of packaging. We use information from CleanMetrics and Meat Eater’s Guide, which provides per kilogram emissions factors for packaging. The third stage is transportation. Calculating transportation emissions requires many simplifying assumptions as transportation emissions are a result of the distance traveled, the mode of travel used, and the carbon intensity of that mode. We obtained average distance traveled and mode for products from CleanMetrics and Meat Eater’s Guide. We assumed the most frequent mode used was the only mode used. We used transportation emissions factors from CE Delft and GHG Protocol. The most common mode was trucking, but we also included container shipping, rail, refrigerated container shipping, and air cargo.

---

5 CleanMetrics is a meta-analysis on US-specific food products.
Finally, because we are looking at emissions at the retail level only, we ignore use and disposal emissions. This is partially because of lack of data, partially to capture consumer response at the point of purchase, and also because for some foods (such as meats) the production phase dominates the use and disposal phases. An extension to our model is described in the Discussion section which would better account for post-purchase decisions such as use and disposal. These phases are more likely to dominate products such as home appliances, electronics, and automobiles.

LCA tends to focus on individual products and specific geographies (for instance tomatoes in Britain) since the emissions from any product can be highly sensitive to whether they are transported, the source of electricity, how much waste there is in the process, etc. Estimating elasticities of demand, however, requires a certain level of aggregation. Thus we find the economic data cover wide groups of products such as ‘non-alcoholic carbonated beverages’ while the carbon footprint of a liter of any soda may depend on whether it is delivered in a 375 mL glass bottle or a 2-liter plastic bottle. Thus to integrate these two data sources, we made simplifying assumptions to calculate the carbon content of broad product categories. For instance, we have separate carbon intensities for brown rice and white rice, which could differ further depending on how they are produced and where they are produced geographically. We thus take an average transportation distance and average the carbon footprint of brown rice and white rice since the quantities consumed of white and brown rice were not available. For other groups, such as other fruits, we used the top groups in these categories for which carbon intensities were available. For other fruits, these were strawberries, peaches, and grapes. We then calculated a weighted average for the aggregated carbon intensity. Ice cream and ice milk had no carbon footprints available for average products but Ben & Jerry’s had calculated their individual footprint per pint. We assumed the density of ice cream was 0.8 grams/mL and calculated the carbon footprint of a pound of ice cream assuming Ben & Jerry’s footprint was representative. For all types of FAFH, we used Carnegie Mellon’s EIO-LCA web model, a sector-based aggregated estimate that calculates emissions on a per dollar basis. The assumption in this model is that the emissions are linearly related to the economic activity.

**Current Carbon Perceptions**

Labels give consumers better information about the carbon content of goods. We model this information as a change in perception. This change in perception is relative to a baseline perception of how consumers perceived carbon footprints pre- and post-labeling. We are unaware of research that documents consumer perceptions of carbon footprints without labels and thus we make a range of plausible assumptions and test the various scenarios. Further research is warranted in this area, as the results are sensitive to how consumers initially calculate their carbon footprint.
We evaluate the effects of carbon labels under three scenarios about current perceptions of carbon footprints. In the first scenario, consumers assume that the carbon footprint per dollar spent on food is the same as the average carbon intensity of the US economy, 0.48 kg/$ (IEA 2011). Thus the consumer contemplating purchasing 0.23 kg of cheese for $1 would assume that this cheese results in 0.48 kg of CO$_2$eq. The label would inform the consumer that 0.23 kg of cheese actually had a carbon intensity of 2.20 kg. The second scenario we test is that consumers have a general idea of which products are carbon intensive but the labels make the carbon cost more salient, which results in an across-the-board 1% increase in the carbon cost of goods. The third scenario we evaluate is the case where consumers initially assume a zero carbon cost of consumption. These assumptions, much like other parts of our model, are meant to be demonstrative of the process and not a definitive statement of the impact of carbon labels on consumer food decisions.

Scenario 1: Consumers assume the carbon footprint across all goods is 0.48 kg/$

To understand the impact of the carbon label we look at the total derivative of emissions with respect to the changes in the perceived emissions of goods:

$$
\psi^{-1} dE = \sum_{i=1}^{N} \left[ E_i \frac{\partial dE_i}{\partial P_i} + \sum_{j=1}^{I} E_j \frac{\partial dE_i}{\partial P_j} \right] dP_i. \tag{3}
$$

This equation specifies the total change in emissions from labeling all goods. If we wanted to know the impact of labeling cheese, we could set $dE_i = 0$ for all other goods and estimate the impact of only changing the perceived emissions from cheese. If we wanted to know the impact of labeling all dairy products, we could set $dE_i = 0$ for all non-dairy products. The total amount of emissions is dependent on the value of $\psi$, thus our results should be interpreted as a way to rank categories of products but not absolute reductions. For simplicity we assume consumers are willing to pay one cent to reduce their carbon footprint by 1 kg, or $\psi = 0.01$. This is presented in Column 1 of Table 4 and the impact of labeling groups of goods is presented in Column 1 of Table 5.

Scenario 2: 1% Increase in the Carbon Cost of All Goods

This scenario corresponds to the case where consumers roughly know what the carbon impacts of goods are, but the labels make the impacts more salient. Since we are assuming that consumers are willing to pay $0.01 to reduce their carbon impact by a kg, this is equivalent to a 0.01% increase in the price of all goods. This is likely an unrealistic assumption to make, but helps bound the actual impact of a carbon label. This is presented in Column 2 of Table 4 and the impact of labeling groups of goods is presented in Column 2 of Table 5.

---

6 This is approximately equal to a willingness to pay of $10/ton of CO$_2$eq reductions.
Scenario 3: Consumers assume a zero carbon cost of goods

In this scenario we assume consumers have been ignoring the carbon cost of all goods, and only take the carbon impact into account once confronted with a label. This is also an extreme assumption to make, but the truth may lie somewhere in between these three scenarios. This is presented in Column 3 of Table 4 and the impact of labeling groups of goods is presented in Column 3 of Table 5.

Discussion

Tables 4 and 5 present simulation results from looking at the impact of labeling each item (Table 4) or groups of items (Table 5) under various assumptions about the current perceptions of carbon footprints. The measurements assume a willingness to pay of $0.01 for a kilogram of person CO₂eq reductions, which is lower than what has been measured in the literature.

We first look at the products associated with the largest reductions in emissions from the label. For instance labeling alcohol (which has a high carbon footprint) results in the largest reduction across all three scenarios. Other meats, which includes many processed meats like sausage and hot dogs, and beef are also good candidates for labeling. In contrast, labeling pork alone results in an increase in emissions since consumers substitute away from pork and into other products that are higher in carbon emissions. However, if consumers are already aware that beef has a relatively large carbon footprint and assume pork has a similar carbon footprint, correcting this misperception so that consumers substitute away from beef and into pork could be an effective carbon mitigation scheme.

Many products will result in an increase in carbon under some scenarios but a decrease in others. Wheat bread is an interesting example of this. When consumers believe that wheat bread has a carbon footprint of 0.48 kg/$, this translates into a perceived carbon footprint of approximately 1.44 kg CO₂eq/kg which is higher than the measured carbon footprint of 0.65 1.44 kg CO₂eq/kg. Thus the label tells consumers that wheat bread is not as carbon intensive as previously believed and hence the consumer consumes more bread under this scenario (and less of its substitutes) but less bread (and more of its substitutes) under the other scenarios.

Labeling certain other items, such as rice, increase emissions under all scenarios. Even in scenario 1, consumers learn that rice has a higher carbon emission than previously thought and so while they use less rice they consume more of the substitutes for rice that are higher in carbon. This is the case with many items in the bread section. One reason for this is because the cross-price elasticities between bread items and meats and FAFH are generally positive. Increasing the mental price of carbohydrates moves consumers from eating these items and into meats and FAFH which have higher carbon footprints.
Extensions

A drawback of our analysis is that the products included are composed of product groups that are heterogeneous in terms of carbon footprints. For example, the product fish and seafood contains lobster, which has a 19.60 kg CO₂eq global warming factor, and cod, which has a 1.19 kg CO₂eq global warming factor. Our model and the set of parameters used can be extended to include more disaggregated products. For the lobster and cod example, assuming that a household chooses these products as a third stage in the budgeting process, one can construct a third stage of lobster, cod, and other fish and seafood using equations (1) and (2) (Figure 1). The parameters necessary to estimate equations (1) and (2) are (a) elasticities of demand for disaggregated seafood and fish products conditional on expenditure for seafood and fish, (b) budget shares of the disaggregated seafood and fish products conditional on expenditure for seafood and fish, and (c) the elasticities of demand from Okrent and Alston (forthcoming). Hence, more precise estimates of the effects of carbon labeling can be estimated with additional information on the products of interest not included in this analysis.

This analysis has ignored use and disposal emissions. A further effort could build a multi-stage analysis where consumers learn the carbon consequences of disposing of food items and packaging as well as cooking and usage patterns depending on cooking method and fuel usage. For instance, a potato cooked in the oven has three times the carbon emissions of a potato cooked in the microwave or boiled on the stovetop (EWG 2011). This can vary by the carbon intensity of fuel sources. We ignore this analysis because we do not have elasticities of demand for potatoes that are baked versus those that are cooked in the microwave. However a survey or study using food diaries may be able to estimate these kinds of elasticities of demand.

Conclusion

This paper is the first to combine information on elasticities of demand and carbon footprints to predict how consumers will respond to new information on carbon footprints. Previous work in the LCA literature has relied on ad hoc assumptions about the willingness to change consumption patterns and what constitutes a substitute for high carbon items. Our model relies on price elasticities of demand to make these decisions and quantifies the substitution and complementary relationships between products, which allows us to calculate reductions in emissions (Tables 4 and 5).

We find that a carbon label on meat and alcohol would yield the largest reductions on total emissions, but some caveats remain. We have ignored consumer heterogeneity and use a fairly aggregated level of analysis. Further disaggregating the analysis to allow consumers to choose between disaggregated products within each food group (e.g., cod versus herring instead of fish versus beef) would likely incur even greater reductions in carbon emissions. In general, we find that goods
where consumers have a low carbon substitute, an inaccurate belief about the carbon footprint of the good, and where high carbon goods have a large market share are the products that are most likely to result in large reductions in carbon just from being labeled.

This paper should not be construed as an argument that carbon labels should replace a carbon tax or cap and trade. Labeling only certain items (e.g. bananas) may have perverse effects in that the label may actually increase total carbon emissions. Labeling also may have spillover effects that result in greater than expected emissions reductions. A comprehensive carbon tax would result in lower overall emissions, be less susceptible to mistakes from an incorrect LCA, and be more transparent than a carbon label system. A carbon label system could however be a complement to an economic instrument or substitute for an economic instrument until more comprehensive climate policy is adopted.
