Sustainability of global and local food value chains. An empirical comparison of Peruvian and Belgian asparagus

Jana SCHWARZ, Monica SCHUSTER, Bernd ANNAERT, Miet MAERTENS and Erik MATHIJS

Abstract
The sustainability of food value chains is an increasing concern for consumers, food companies and policy-makers. Global food chains are often perceived to be less sustainable than local food chains. Yet, thorough food chain analyses and comparisons of different food chains across sustainability dimensions are rare. In this article we analyze the local Belgian and global Peruvian asparagus value chains and explore their sustainability performance. A range of indicators linked to environmental, economic and social impacts is calculated to analyze the contribution of the supply chains to economic development, resource use, labour relations, distribution of added value and governance issues. Our findings suggest that none of the two supply chains performs invariably better and that there are trade-offs among and between sustainability dimensions. Whereas the global chain uses water and other inputs more intensively and generates more employment per unit of land and higher yields; the local chain generates more revenue per unit of land.

Key Words: local food value chains, global food value chains, food trade, asparagus, sustainability

Sustainability of global and local food value chains. An empirical comparison of Peruvian and Belgian asparagus

1 Introduction

Consumers are increasingly concerned about the sustainability performance of their food consumption (Feldmann and Hamm 2015, Meas et al. 2015). A particular consumers’ choice is between food products that are sourced locally and global food products. Global food products are often perceived to be less sustainable than local food products – a perception that is confirmed by concepts such as ‘food miles’, ‘think global, eat local’, ‘short food chains’, ‘local food systems’ and ‘local-food movements’. Yet, the evidence on the sustainability performance of local versus global food chains is mixed and often focussing on one single component of sustainability. The largest part of the evidence comes from environmental impact models that compare domestic and imported food, in terms of ‘food miles’ and related differences in greenhouse gas (GHG) emissions. For example, Stoessel et al. (2012) use Life Cycle Assessment (LCA) to find very high carbon emissions related to asparagus and papaya imports by airfreight compared to local fruits and vegetables. Also Van Hauwermeiren et al. (2007) find a large difference in energy use and resulting carbon emissions between imported versus domestic food, but highlight that consumers’ purchasing behaviour and in-season production also play an important role for emissions. Other authors also conclude that seasonality is an important element when comparing GHG emissions, as their findings suggest that the duration and form of storage between production and consumption have large impacts on total emissions (Edwards-Jones 2010, Milà i Canals et al. 2007). By applying general equilibrium modelling, Avetisyan et al. (2014) highlight that differences in regional emission intensities related to on-farm production of ruminant livestock have a much bigger impact on global GHG emissions than changes in transport-related emissions. In this respect, there is no straightforward universal answer to the total environmental impact of local versus global food consumption.

A second stream of the literature focuses on the economic impact of consuming local or global food and the exclusion or inclusion of farmers, as well as workers in these value chains. It has been shown that consumers prefer local food to support regional farms and local economic activities (Meas et al. 2015) and that local value chains have positive impacts on the local economy through multiplier effects (Swenson 2010), employment creation and economic gains (Hughes et al. 2008). Ballingall and Winchester (2010) assess increasing consumption of local food from a different angle and examine the potential impact of
reducing imports in the UK, Germany and France on welfare in the countries of origin of the imported products. They find the largest welfare loss relative to GDP in New Zealand, Malawi and Madagascar. It has also been shown that the participation of low- and middle-income countries in international trade can have positive development impacts through economic growth and poverty reduction (Dollar and Kraay 2004). Positive income effects for the local population may happen through inclusion of smallholder farms in global food value chains and creation of employment possibilities for rural households (Maertens et al. 2011, Maertens and Swinnen 2009, Asfaw et al. 2009).

Relatively few studies analyze social impacts of local versus global food supply chains. One strand of the literature focuses on low-income countries and finds positive impacts of the inclusion of farmers in export supply chains on happiness (Dedehouanou et al. 2013), on primary school enrolment (Maertens and Verhofstadt 2013) and on food security (Bellemare and Novak 2015). Regarding the creation of employment opportunities, Van den Broeck and Maertens (2015) find that female labour market participation reduces fertility rates. It has also been shown that increasing compliance with private labour standards improves labour conditions in food export chains (Schuster and Maertens 2016). Some studies express specific concerns about the kind of employment that is created and highlight that the overall well-being of workers in high-value export chains crucially depends on the quality of employment (Barrientos et al. 2011, Selwyn 2013). Other concerns relate to the exclusion of the poorest farmers from global value chains and increasing inequality due to high food quality and safety requirements (Asfaw et al. 2010, Handschuch et al. 2013). Regarding social impacts of local supply chains Macias (2008) claims that local agriculture can have positive impacts on food equity, social integration, and experiential knowledge of nature.

Most of the above cited studies focus on only one single sustainability dimension or use only one methodology to assess food chain performance such as LCA or Input-Output analysis. There are some studies that apply multidimensional sustainability analysis to local food systems using qualitative indicators (e.g., Peano et al. 2015). Quantitative studies comparing the performance of local and global food supply chains across dimensions are rare. In this article we explore the sustainability of local and imported asparagus considering environmental, economic and social impacts. We take a multidimensional approach and combine different methods for analyzing two case studies in depth: first, a chain of asparagus produced and consumed in Belgium, and second, a global chain of asparagus produced in Peru and exported to Belgium. The analysis focuses on asparagus, a vegetable historically grown during a short season in Belgium, and with a high importance as export crop in Peru.
Both are sold to Belgian consumers who can buy domestic asparagus seasonally or imported asparagus the whole year round. The paper is structured as follows. In the next section, we present the materials and methods including the choice of sustainability attributes and indicators for our analysis, and data collection methods. In sections 3 and 4 we describe the Belgian and the Peruvian asparagus sector in detail, including the identification of the most critical sustainability issues in each chain. The results of our analysis are presented and discussed in section 5. Section 6 concludes.

2 Materials and Methods

A universally accepted definition of local food does not yet exist. Often, the local-global dichotomy is based on the geographical distance between producer and consumer and the supply chain configuration, such as the number of supply chain steps and the kind of marketing channel (e.g., Van Hauwermeiren et al. 2007, Galli et al. 2015, Taillie and Jaacks 2015). But the maximum distance at which a product changes from being ‘local’ to being ‘global’ is not clearly defined. In some studies, local food refers to food that has been grown within a country’s boundaries and global food refers to imported products (Milà i Canals et al. 2007, Blanke and Burdick 2015). In other cases, ‘local’ food is defined as food that is grown and consumed within a county (Swenson 2010), or that is marketed through a short supply chain, such as a farm shop, a farmers’ market or a CSA (community supported agriculture) system (Van Hauwermeiren et al. 2007, Santini and Gomez y Paloma 2013). International sourcing of production inputs for locally produced and consumed products complicates the distinction of “local versus global” (Feldmann and Hamm 2015). In this article we follow the definition based on national boundaries and distinguish between a local chain including production and consumption of asparagus in Belgium, and a global chain including production of asparagus in Peru and export to Belgium.

The framework of our analysis is formed by five attributes related to the sustainability performance of food supply chains. Each attribute is measured by a set of indicators.

2.1 Sustainability attributes and performance indicators

We consider five attributes related to the social, economic and environmental sustainability of asparagus chains: contribution to economic development, resource use, labour relations, distribution of added value and governance. They have been selected from a list of food chain performance attributes that has been elaborated by Kirwan et al. (2014) based on 12 national reports on the perception of food chain performance in European countries, Senegal and Peru. Our attribute selection is based on the most critical issues that have been identified through
literature review, discourse analysis and stakeholder interviews in Peru and Belgium. These issues, namely water use, labour relations and the role of standards and certifications are described in further detail in sections 3 and 4. The selection of the attributes *contribution to economic development* and *distribution of added value* follows from the fact that Peru is a middle-income country and increasing trade might have considerable development impacts. For each attribute we have defined a set of indicators to assess and compare the performance of the two asparagus supply chains. Most indicators have been adapted from a list of 118 indicators elaborated in the SAFA (Sustainability Assessment of Food and Agriculture systems) Guidelines (2013a, 2013b). They provide a holistic framework for the sustainability assessment of food and agricultural supply chains based on four broad dimensions of sustainability: good governance, environmental integrity, economic resilience and social wellbeing. Our analysis includes the following attributes and related performance indicators.

First, the attribute *contribution to economic development* refers to the contribution that food supply chains can make to economic development at a national, regional and local level. This attribute is especially important when thinking about possible positive development effects of a global food supply chain. The consumption of imported products in Europe can have positive impacts on economic development overseas. At the same time, the consumption of local products supports the local economy. The attribute is represented through four indicators. (i) *Regional employment generation* indicates the number of full-time equivalent workers employed for field work and processing activities such as cleaning and packaging per ha of asparagus production. It shows how the asparagus chains contribute to local value creation through employment opportunities and thus, wages. (ii) *Regional hiring* measures the share of farm workers who come from outside the production region. In Belgium, these are workers who come from other countries. In Peru, these are workers that do not come from one of the asparagus producing departments. Hiring employees from the region where operations are based contributes to sustaining the local economy (FAO 2013b). (iii) *Economic land productivity* measures the economic value generated per unit of land use. (iv) Similarly, the indicator *economic labour productivity* compares the economic value generated per farm worker in the two countries.

Second, the attribute *resource use* has been selected due to its relevance mainly for the Peruvian asparagus sector which relies heavily on scarce water resources. The use of energy, land and labour also fits into the scope of this attribute. Differences in climate and production methods lead to differences in the ecological efficiency of asparagus production in the two countries, making it interesting to assess the overall efficiency of resource use of local and
global chains including economic and ecological aspects. The attribute is measured with six indicators. (i) Physical land productivity indicates differences in yields per ha between Belgium and Peru while (ii) physical labour productivity measures the yield per farm worker. (iii) Greenhouse gas emissions related to asparagus transportation are calculated to reflect food miles and carbon emissions of the two chains. The indicators of water use per tonne (iv) and per ha (v) measure the volume of consumptive water use through evapotranspiration, i.e. the water footprint of production (Mekonnen and Hoekstra 2010) relative to the yield and the land use, respectively. (vi) Water withdrawal puts the water use of the asparagus sector into context relative to the total water withdrawal of the national agricultural sector.

Third, the attribute labour relations refers to employment relations and working conditions which might differ between Peru and Belgium due to institutional differences. All indicators refer to workers at the farming and processing stage where most employment is generated. (i) The indicator wage level compares workers’ average wage to the local living wage. (ii) Wage payment refers to the percentage of workers who receive at least the domestic minimum wage. (iii) The indicator collective bargaining and association is measured through the percentage of workers who are members of a labour union. It indicates whether workers have the freedom to associate to efficiently negotiate working relations (FAO 2013b). (iv) The indicator work contract indicates the share of workers who have signed a legally binding work contract and (v) working hours compares actual working time with regular working time on a daily and weekly basis. (vi) The percentage of workers with access to clean sanitary facilities and drinking water is used to quantify decent working conditions.

Fourth, distribution of added value refers to how value is distributed within the food value chain. This is expected to differ between local and global chains mainly due to differences in the number of supply chain actors, their bargaining and market power. The attribute is represented by the indicator revenue distribution which measures the price a farmer receives relative to the price the consumer pays in the supermarket.

Fifth, governance refers to regulation and governance structure and to power and democracy (Kirwan et al. 2014). Public and private standards emerged to address increasing quality and safety requirements of consumers on agricultural products. Whereas public standards are set by public authorities and focus mainly on food safety and quality, private standards are set by private companies and non-public organizations and add environmental and ethical aspects (Henson and Humphrey 2010). In the asparagus case, the attribute governance relates especially to private standards, certification and labels in governing food supply chains. Two variants of the indicator certification are calculated. (i) The percentage of certified producers
and companies that comply with at least one private standard and (ii) the percentage of certified produce.

Table 1 summarizes the indicators per sustainability attribute. We provide a short definition and the data sources used for calculation. In the section 2.2 we describe the data collection methods in detail.

2.2 Data

Qualitative and quantitative data were collected in Peru and Belgium through interviews, surveys and secondary data collection.

First, qualitative unstructured interviews with key respondents and stakeholders involved in the Peruvian and the Belgian asparagus supply chain were carried out. These interviews have not followed a predetermined structure, but have been used to get a better understanding of the asparagus sector, the functioning of the supply chains and to identify critical issues. In Peru, fifteen asparagus producers – ranging from a cooperative of small scale farmers over medium sized companies to the two largest agro-export companies – have been visited and interviewed. Different water use organizations, the National Water Authority (ANA) and the Chavimochic project – a huge irrigation project along the Peruvian coast covering more than 140,000 ha – have been visited in order to discuss water related issues such as the overexploitation and distribution of water resources in the agricultural sector. Government officials (e.g., ministry of agriculture and ministry of labour and employment promotion), policy institutes (e.g., IPEH, PROMPERU), logistic operators (e.g., Frio Aereo; transport intermediaries) and researchers have been interviewed regarding critical issues of the asparagus supply chain. Different NGOs that support farm workers in the agro-export industry and smallholders have been visited. In Belgium, we met with representatives of one large Belgian importer and one Belgian retailer to discuss their asparagus supply chain configuration. In addition, field visits have been paid to asparagus farmers in Flanders and to BelOrta – Europe’s largest cooperative auction and the most important auction for Belgian asparagus. We have interviewed a representative of the national farmers’ association responsible for vegetable growers. Interviews and farm visits in Peru took place between January and February 2011, in April 2013 and between February and April 2014. In Belgium, interviews were conducted between May and October 2014. Primary quantitative data have
been collected together with the qualitative interviews. The quantitative data includes the quantities of inputs used in the production process, prices and time series of cultivated areas. Second, we use data collected through surveys. In Peru, 95 asparagus export companies have been surveyed between July and September 2011. The questionnaires included recall questions on certification to private food standards, on ownership and management structure, on processing and production procedures, and on sourcing and marketing strategies. Moreover, two rounds of a survey among young workers in the horticultural agro-export industry in the regions of Ica and La Libertad have been carried out in August/September 2013, and in February/March 2014. In that survey, questions have been asked on the workers’ socio-demographic background, economic and employment situation, health, education, overall wellbeing, and employment and working conditions. In the first round, 592 workers have been surveyed. In the second round, 528 workers of the original sample could be resurveyed and 85 additional workers have been surveyed only in 2014. In Belgium, a small survey of three Flemish asparagus farms has been carried out in September/October 2014 in order to gather information on asparagus production practices, resource use, labour relations, prices and other supply chain characteristics. The large difference in the number of observations is mainly due to large differences in size of asparagus production in Peru and Belgium.

Third, information has been collected from a literature and document review and from publicly available trade (Faostat; SUNAT – custom data) and agricultural production databases (INEI 2012). There are some previous studies on the Peruvian asparagus sector, mostly focusing on the production and processing stage. There is hardly any literature on the Belgian asparagus sector due to its limited economic importance.

3 Belgian asparagus

3.1 Value chain description

Figure 1 shows the Belgian asparagus value chain. In 2013 there were 157 asparagus producers in Belgium of which 137 have their holding in Flanders. The area devoted to asparagus production has nearly doubled between 2009 and 2013, from 174 ha to 326 ha (Statistics Belgium 2014), but remains small in the total agricultural area of more than one million ha in Belgium. Growers usually only dedicate part of their agricultural land to asparagus production and also cultivate other vegetables such as leek. Yields have increased from around 6 tonnes/ha at the beginning of the 2000’s to around 9 tonnes/ha in 2012 (Faostat 2015). Predominantly white asparagus is grown. In 2014, only one farmer cultivated green
asparagus on 17 ha (BelOrta 2014a). Regarding production techniques, only 9 ha of asparagus have been grown in a greenhouse in 2014, the remaining production takes place in open field. Given an average labour input of 1.56 workers per ha (see section 5), the Belgian asparagus sector provides on-farm employment to around 500 workers.

**Figure 1: Belgian asparagus value chain**

Asparagus harvest takes place between beginning of April and mid-June. After harvest the asparagus is processed, i.e. it is bathed and sorted based on 5 classes of thickness and 4 classes of form. The higher quality asparagus is generally delivered to a cooperative auction where the product is inspected for quality, weight, size and packaging. Then the asparagus is grouped according to quality codes and stored until it is sold. The best quality asparagus (with the form ‘straight and white’ and thickness category A (16-22mm) or AA (22-28mm)) receives the Flandria quality label after inspection by an auction official. The leading auction for asparagus is the BelOrta auction situated near the city of Mechelen in the province of Antwerp. On average, the auction sells 2 million kg of asparagus per year. In the sales hall of the auction fruits and vegetables are offered to the buyers, many of which are retailers. The auction starts with a high price which then descends until the first buyer concludes the transaction. In 2013, the average price received by farmers for Flandria asparagus at the auction was 3.75 EUR/kg. For the lower quality code B asparagus (12-16mm) farmers received 1.60 EUR/kg. Nearly immediately after the sale has been concluded the product is ready to be collected by the buyer, many of which retailers. Other buyers include exporters, wholesalers or restaurants, for instance. After being sold at the auction the asparagus is distributed and sold to the consumer.
A part of the production, often the lower quality asparagus, is sold directly to the consumer on-farm. This marketing channel is very common in the asparagus sector and of increasing importance for the growers. For code B asparagus farmers can receive 5 EUR/kg, considerably more than at the auction. However, farmers who are auction-members are obliged to supply the high-quality asparagus to the co-operative. Finally, some farmers sell their produce directly to retailers and other buyers before it reaches the consumer.

3.2 Case study context and critical issues

3.2.1 Global-local issues
Belgian asparagus is a very seasonal product with a very short harvest season from the end of April to June. It is only grown in specific regions in Belgium due to soil quality requirements and sold mainly within the country. This is especially the case for asparagus sold at the farm shop to consumers who generally live in the vicinity. During the past years, the amount of asparagus sold directly on the farm has increased a lot (Boerenbond 2014). But there are also some global aspects in asparagus production. The rhizomes are imported from nurseries in the Netherlands and often the transplanting is also done by external Dutch companies. Moreover, the largest share of seasonal workers for harvesting and packing comes from Eastern European countries. Thus, the local product depends on input supplies from other countries.

3.2.2 Standards and certifications
In order to sell their product to an auction, asparagus farmers need to comply with GlobalGAP and the Vegaplan standard, basic production standards including food safety and traceability requirements. For instance, GlobalGAP includes compliance criteria for all stages of production, from pre-harvest activities such as soil management and fertilizer use to post-harvest activities like packing and storing. The BelOrta auction holds a group certificate for asparagus including a producer group of 86 farms (GlobalGAP 2014). This means that all producers have to comply with the standard, but external certification costs are lower than in the case of individual certification. Compliance with GlobalGAP and Vegaplan is required for obtaining the Flandria quality label which includes requirements on (i) cultivation practices such as planting material and fertilizers used, (ii) quality standards such as the shape of the product and the absence of foreign products, and (iii) traceability and control in order to be able to trace each product from the soil to the consumer (BelOrta 2014b).
4 Peruvian asparagus

4.1 Value chain description

Peru is the largest exporter of asparagus worldwide. The sector currently accounts for about 25% of the country’s total agricultural exports (SUNAT 2015) and has thus an important role in the national economy and the labour market in the production regions. Exports of asparagus more than doubled between 2000 and 2013, amounting to nearly 185,000 tonnes in 2013 and earning Peru more than 600 million USD FOB (SUNAT 2015). The product is exported fresh (around 70% of all production), preserved (around 25%) or frozen (around 5%) and all forms require a selection, cutting and packaging procedure in a local processing plant. There is no domestic market for asparagus and 99% of the entire production is exported. The main destination markets are European countries (25% of all fresh; 26% of all frozen and 71% of all preserved produce) and the United States (70% of all fresh; 51% of all frozen and 22% of all preserved produce) (SUNAT 2015). The asparagus production area ranges from 300 km south (Ica region) to 600 km north (La Libertad region) of Lima along the desert coast. Both green and white asparagus is produced but the production of green varieties outnumbers the production of white asparagus (83% green vs. 17% white (Benson 2009)). Due to the favourable climate in the production regions, asparagus yields on average 11.4 tonnes per hectare per year, being among the highest yields in the world (Faostat 2015). Depending on the region two to three harvests are possible per year (O’Brien and Díaz Rodriguez 2004).

Despite the long distance between production and consumption of the product, the Peruvian asparagus value chain is highly vertically integrated. Figure 2 presents an overview on the Peruvian asparagus supply chain. It is characterized by modern inputs, latest production, processing and transport technologies and conform to international quality standards. Most agricultural inputs, such as seeds, agrochemicals and machinery are imported, while agricultural production and processing takes place in different coastal regions in Peru. After processing, the produce is transported to the Constitutional Province of Callao, from where it is either shipped from the harbour of Callao (99% of all preserved produce in 2011) or the Jorge Chavez international airport (86% of all fresh produce in 2011 (SUNAT 2015)). In 2011, in Peru there were 131 agro-export companies that sold to international importers; they can be further divided into four categories: 1/ Fully vertically integrated export companies with own production and processing (54 companies), 2/ Export companies with production but without processing capacities (10 companies), 3/ Export companies without own production but processing (13 companies) and 4/ Pure trading companies (54). As all exported
product is processed, companies that do not own a processing plant, but export, rent in capacity from external processing companies. Alternatively, pure producers sell their product to vertically integrated export companies or on the spot market to traders and processors (Schuster and Maertens 2013). According to the latest agricultural census in 2012 (INEI 2012) and our own survey there are nearly 3,209 asparagus growing entities that produce but do not export directly. The size of production units varies between 1 and 1,600 ha. The largest share of producers (around 80%) grows asparagus on up to 50 ha, 17% cultivate between 6 and 50 ha and 3% more than 50 ha. The size of cultivated asparagus land of only the vertically integrated companies is considerably larger, with an average of around 450 ha; four vertically integrated companies grow asparagus on more than 1,000 ha. While the annual number of exporters is relatively constant and fluctuates around 100 companies, in total 656 companies ever exported asparagus from Peru between the years 2000 and 2014 (SUNAT 2015). This indicates a large entry and exit of the export market of - mainly trading – companies that easily adapt to temporary market conditions. The number of asparagus importers fluctuates between 350 and 490 over time, with a similar amount of buyers from the US and Europe (169 and 176 respectively in 2011(SUNAT 2015)). In Belgium in 2011, there are five main importers of asparagus from Peru. Together, these companies cover more than 80% of Belgian imports and bought 1,251 tonnes of either fresh or preserved asparagus (SUNAT 2015). The majority of the fresh asparagus is flown to the Amsterdam Schiphol airport, while the preserved asparagus is shipped to the ports of Rotterdam or Hamburg. From there, the

asparagus is transported by truck to the wholesaler’s or supermarket’s central distribution centres in Belgium

4.2  Case study context and critical issues

4.2.1  Water issues

A critical issue associated with the Peruvian asparagus supply chain is the use of scarce water resources for the production of export crops. This is especially crucial bearing in mind that asparagus production takes place in the Peruvian coastal regions under desert conditions and that asparagus production consumes relatively high amounts of irrigation water. Per hectare and year, asparagus producers in Ica need around 14,500 m$^3$ of irrigation water using drip irrigation techniques and 23,000 m$^3$ using flood irrigation (MINAGRI 2015). In Peru in 2012, on 54% of the asparagus land drip irrigation has been used and on 44% of the land flood irrigation has been applied. The remaining area has been irrigated using sprinkler and exudation irrigation (INEI 2012).

Water related problems differ between the two largest asparagus production regions. In Ica, irrigation water for asparagus cultivation is mainly pumped from groundwater resources as surface water availability varies strongly with the seasons and irrigation water demand exceeds availability. The heavy reliance on groundwater resources from the local aquifer leads to the decrease of the groundwater table of up to 1.5 m per year on average (ANA 2012) and depending on the location the depth of perforation is deeper than 100 m below the surface (MINAGRI 2015). In order to slow down the overexploitation of the aquifer the ANA has prohibited the perforation of new wells and to deepen existing ones (ANA 2012). The water stress in Ica has been the subject of critical NGO reports, blaming the asparagus export industry for being responsible for unsustainable water extractions (Hepworth et al. 2010). Besides ecological threats of groundwater overexploitation, water scarcity also has negative economic implications for the agro-export companies themselves because water is the limiting factor of production.

In La Libertad, a large irrigation project named Chavimochic – covering the valleys of Chao, Virú, Moche and Chicama – has been implemented since the 1960s. The project brings water from the Santa River to the coastal valleys and has thus been crucial for the transformation of deserts into agricultural lands. However, it is criticised that the project has mainly benefited large export companies and not small farmers. Between 1994 and 2006 nearly 44,000 hectares of new land have been developed, of which nearly 38,000 hectares have been bought by 11 agro-industrial companies (Burneo 2011).
4.2.2 Labour relations

Two important laws increased the competitiveness of the agro-export sector, by lowering labour costs. First, the ‘Decree Law 22342’ provides non-traditional export companies, including asparagus exporters with flexibility in hiring; it allows an open-ended employment of workers on short-term contracts, as well as the possibility to legally suspend employees if agricultural seasonality requires it. Second, the ‘Agricultural Sector Promotion Law 27360’ establishes a special labour regime for agricultural workers, stipulating lower rights and benefits for workers in export-oriented non-traditional agri-food businesses; such as lower wages, contributions to the social security system and reduced annual leave.

From a social and ethical perspective, issues related to working conditions and labour welfare in the Peruvian asparagus chain are debated. On the one hand, asparagus production and processing is very labour intensive and provides considerable employment opportunities in the production regions. The two above regulations have contributed to reducing the cost of hiring temporary workers, resulting in an increase in the absolute number of - mainly low-skilled - employees, but also formally registered jobs (Chacaltana 2007); 60% of all employees are estimated to be women. This has led to an agricultural wage increase in the export sector, which, according to Cannock (2011) are around 30% higher than wages in local agriculture. On the other hand, some stakeholders heavily criticize both above laws because of decreased protection of labour rights in the agro-industry (Ferm 2008). Wages are said to be still extremely low and often only paid on piece rates. Employment is often temporary and no job security is guaranteed to workers throughout the whole year. Moreover, concerns about bad working conditions and labour right violations such as discrimination against union members, long working hours and dismissal of workers during ‘seasonal recessions’ have been raised (e.g., USLEAP 2013).

4.2.3 Role of private standards and certifications

Private standards started to gain importance in the Peruvian asparagus export sector in the year 2000 and certification to these standards by companies has spread rapidly in the sector from then onwards. While until 1998 no export company was certified, certification takes off from the year 2000 and since 2006 the number of companies certified to at least one private standards exceeds that of non-certified companies (Schuster and Maertens 2015). These

---

1 Other non-traditional export sectors include some agriculture, livestock and textile products, but also fishing, wood and paper, chemical, metallurgic and non-metallic mining products.

2 Specifically, this includes 15 days of annual vacation (instead of 30 days as in the general labour regime), 4% contribution to social security by the employer (instead of 9%), a minimum wage of 29.26 PEN/ day instead of 750 PEN/ month but which includes the severance pay and the Christmas and national holiday bonus, a compensation of arbitrary dismissal of 15 days’ pay per year worked (instead of 45 days). (PLADES 2012)
private standards are diverse and include pre-farm gate or production standards as well as post-farm-gate or processing standards. Basic standards focus on quality and safety issues while more specific standards that emerged towards the end of the 2000s focus on environmental and social issues related to the production, processing and distribution of food. Companies in the sector are often certified to multiple standards, first adopting more basic production and processing standards (such as GAP, GlobalGAP, or HACCP) and later more specific standards related to environmental and labour issues (such as SA8000 – see Schuster and Maertens 2016). This has increased the reliability and efficiency of the asparagus supply chain. The fact that the asparagus has been produced in Peru is not used as a sales argument in marketing. On the sales’ label the origin of the product is indicated, but generally there are no further label specifications for differentiating Peruvian asparagus from asparagus originating in other countries.

4.2.4 Role of public policies and institutions
International cooperation and public policies have played a prominent role in supporting the growth of the Peruvian asparagus sector. In the mid-1980s, asparagus export expanded considerably as a result of a U.S. Agency for International Development (USAID) assistance project in the region of Ica. In the 1990s, multiple government operations under president Fujimori created an institutional framework to increase the competitiveness of the agro-export sector and thus, foster economic development (Díaz Rios 2007). More specifically, institutions and policies have been created that facilitate access to land and water resources, improve export infrastructure, increase export quality to meet international standards, enable foreign direct investment and provide cheap labour inputs. Reforms led to the establishment of institutions such as the Promotion Agency of Peru (PROMPERU) in 1993, the Peruvian Export Promotion Agency (PROMPEX) in 1996, the National Agrarian Health Service (SENASA) in 1992 and the Peruvian Institute of Asparagus and Vegetables (IPEH) in 1998. These institutes have significantly supported Peruvian companies in becoming key players in the international market and have acted as an important communication channel for local and foreign government agencies.

Besides these collaborations and initiatives of the agro-industry and the state, specific laws have influenced the asparagus value chain and helped to increase Peru’s comparative advantage. The 1991 ‘Foreign Investment Promotion Law’ led to the equal treatment of foreign and domestic investors and liberalized land markets. This has not only attracted

---

3 PROMPEX was merged with PROMPERU in 2007.
foreign investment but also investors from other Peruvian sectors, such as mining. The ‘Agricultural Sector Promotional Law 27360, introduced in 2000 and recently extended until 2021, as well as the ‘Decree Law 22342’, in place since the 1970s, have reduced the tax burden for agricultural companies and significantly lowered agricultural employment costs (see ‘labour relations’ above). At the international level, free trade agreements (FTAs), especially with the US and the EU, have provided the basis for the tremendous growth of the Peruvian asparagus sector. In the early 1991 the Andean Trade Promotion and Drug Eradication Act (ATPDEA) came into force which granted Peruvian asparagus exports tariff-free access to the US market. An FTA has been signed with the US in 2006. The EU-Peru FTA has been signed in June 2012 and led to the reduction of tariffs for fresh asparagus from 10.2% to 0%. On average, tariffs have been reduced from 66% in July 1990 to 3.4% in 2011 due to unilateral reductions and FTAs (Cannock 2011).

5 Results and Discussion

5.1 Indicators

The main result of our research is a list of indicators to quantify and explore the sustainability performance of the Belgian and the Peruvian asparagus value chain. It is very important to take into account the case study context information when interpreting and comparing indicator values for the two countries. Below, we explain the underlying calculation steps for each indicator. Table 2 summarizes our results.

Regional employment generated
The number of workers per ha in Belgium has been obtained from farm interviews. In our sample on average 1.56 workers are employed for working on the fields and for carrying out processing activities. Given 326 ha of asparagus land this leads to 509 full-time equivalent jobs. In Peru, on average 1.5 field workers are employed per ha and 18 worker-days are needed to process one tonne of asparagus (Danper n.d.). Given 33,673 ha of asparagus production and 383,144 produced tonnes from Peru in 2013 (Faostat 2015), 50,510 full-time equivalent field workers and 21,286 full-time equivalent processing plant workers are required. This adds up to a total of 71,796 workers and 2.13 workers per ha.

Regional hiring
For Belgium, the share of migrant workers on asparagus fields has been estimated being 99% by a representative of the farmers’ union. Migrants in this case are defined as people not having their permanent residence in Belgium. For Peru, migrants are defined as coming from
a department other than the asparagus producing department (i.e., Ica or La Libertad) and the information comes from the worker survey.

**Economic land productivity**

Economic land productivity has been estimated for 2013 by multiplying the quantity produced (Faostat 2015) with the producer price (Faostat 2015) and dividing the product by the acreage used for production (Faostat (2015)) for Peru and Statistics Belgium (2014) for Belgium. The producer price has been converted to international USD using the 2013 average annual exchange rate and the PPP conversion rate provided by the World Bank\(^4\). For Belgium, the farm gate price is 3,118.7 USD/t which results in 2,763.43 international USD/t. For Peru, the producer price of 1,130.25 USD/t converts into 2,028.8 international USD/t.

Belgium: \((2,800 \text{ t} \times 2,763.43 \text{ int’l USD/t})/326 \text{ ha}=23,735 \text{ int’l USD/ha}\)

Peru: \((383,144 \text{ t} \times 2,028.8 \text{ int’l USD/t})/33,673 \text{ ha}=23,084 \text{ int’l USD/ha}\)

**Economic labour productivity**

Economic labour productivity has been estimated by multiplying the total annual production with the producer price (Faostat 2015) and dividing the product by the number of field and processing plant workers. It has been calculated for the year 2013 and indicates how much value is generated by one farm and processing worker per year. Costs are not considered. As above, USD have been converted into international USD.

Belgium: \((2,800 \text{ t} \times 2763.43 \text{ int’l USD/t})/509 \text{ workers}=15,202 \text{ int’l USD/worker}\)

Peru: \((383,144 \text{ t} \times 2028.8 \text{ int’l USD/t})/71,796 \text{ workers}=10,827 \text{ int’l USD/worker}\)

**Greenhouse gas emissions**

The calculation of GHG emissions relates only to the transport phase of the asparagus from the producer to a store in Brussels. Peruvian asparagus is transported by truck from the production regions to Lima. Then the asparagus is transported by plane to Amsterdam and then by truck to Brussels. In total, this amounts to 650 km by truck and 10,000 km by plane. For Belgian asparagus we assume transportation by truck from the production region Hamont-Achel to the BelOrta auction in Mechelen and from Mechelen to Brussels. This amounts to 164 km of road transport.

GHG emissions for freight transport by plane and by truck come from the ecoinventv3.0 database in Simapro ©. Embedded emissions for manufacturing the truck and plane and for the necessary infrastructure are also included in the database. The total impact in kg CO₂ equivalents per kg of asparagus was calculated based on the Recipe midpoint method. We multiply the impact in kg CO₂ equivalents per tonne.kilometre for each transport method (1.1 by airplane and 0.178 by truck) with the transport distance. By summing up the emissions of each transport phase we obtain the total emission of CO₂ equivalents, 0.03 for Belgium and 11.12 for Peru. This is in line with a total impact of 12.2 kg CO₂ equivalents/kg air freighted Peruvian asparagus that was calculated by Stoessel et al. (2012) including agricultural production.

**Physical land productivity**

Faostat (2015) provides worldwide annual yield data by crop and by country (t/ha). This indicator was directly taken for asparagus yields in Peru and Belgium. The latest data are available for the year 2013.

**Physical labour productivity**

For calculating labour productivity we use production data from Faostat (2015) for the year 2013. By dividing production by the total number of full-time equivalent workers that has been calculated for the indicator regional employment generated, we receive the productivity per worker in 2013.

Belgium: 2,800 t/509 workers=5.5 t/worker
Peru: 383,144 t/71,796 workers=5.34 t/worker

**Water use**

Mekonnen and Hoekstra (2010) have estimated the average national and subnational water requirements of a number of different crops and countries. Their estimates include all the water a plant needs for evapotranspiration and are calculated on a 5 arc minutes spatial scale. We take the average national water consumption of asparagus produced in Belgium and Peru. The water use efficiency per ha is calculated by multiplying the efficiency per tonne with the yield per ha obtained from Faostat (2015).

Belgium: 889 m³/t
889 m³/t*7.65 t/ha=6,801 m³/ha
Peru: 1,137 m³/t

1,137 m³/t * 11.38 t/ha = 12,939 m³/ha

**Water withdrawal**

The water withdrawal has been calculated by multiplying the total asparagus production of 2013 with the average blue water footprint (i.e., the consumption of surface water) (Mekonnen and Hoekstra 2010). This volume is then divided by the annual water withdrawal of the national agricultural sector (Aquastat 2015). For Belgium, the latest information is provided for the year 2009 and the volume of water withdrawn by the agricultural sector amounted to 0.04*10⁹ m³/year. In Peru, the latest data is for the year 2008 and the volume of water withdrawn amounts to 12.12*10⁹ m³/year.

Belgium: (2,800 t*17.16 m³/t)/(0.04*10⁹ m³)*100 = 0.12%
Peru: (383,144 t*478.48 m³/t)/(12.12*10⁹ m³)*100 = 1.51%

**Wage level**

For Belgium, we assume that the wage level for agricultural workers is compliant with the national minimum wage of 851 EUR/ month or 1157 USD/month as we do not have accurate data for this indicator. In Peru, the average monthly wage received by the workers in our sample in Peru is 901 PEN or 317 USD⁵.

We divide these values by the respective local living wage for one person in Peru and Belgium as estimated by wageindicator.org for the year 2014. We take the upper bound estimate of the living wage which is defined as “the monthly net wage needed [to] afford a decent standard of living for the individual worker” in the most expensive part of the country. This is done as the coastal region in Peru is among the most expensive areas in Peru. The living wage includes “cost of food based on local consumption pattern[s], a monthly rental of an apartment in a non-central area, transportation costs and 10% allowance for other costs (clothing, medical care, education, culture...)”.

Belgium: 1157 USD / month / 1006 USD / month = 1.15
Peru: 317 USD / month / 159 USD / month = 1.99

A value of one would indicate that the monthly wage covers exactly the living cost.

---

⁵ Average exchange rates between August 2013 and April 2014, period of the worker survey (Oanda.com)
**Wage payment**

For Belgium, we assume that practically all workers are paid the minimum wage (99%). In Peru, we know from our quantitative worker survey that 77% of our sampled workers are paid at least the national minimum wage of 750 PEN/month or 264 USD/month.

**Collective bargaining**

In Belgium, no reliable quantitative information exists for this indicator; yet, there is very little workers’ organization because of the seasonality and high presence of migrants in the sector (Boerenbond 2015). We therefore assume this indicator to be lower than 2%. For Peru we do not have specific data on asparagus only, but on all horticultural export companies producing a variety of export crops, among which asparagus. In 2013, five horticultural companies in Ica and three in La Libertad had a trade union, with 328 and 1,160 members respectively (FENTAGRO 2013). This represents less than 1.5% of the total population of horticultural field and processing plant workers. We assume that this percentage is the same for asparagus workers only.

**Work contracts**

For Belgium we assume that all farmers comply with the law and thus, almost all workers have a work contract (99%). In Peru, we know from our quantitative worker survey that 68% of our sampled workers sign a formal employment contract; one third of the workers thus have no job security at all.

**Working hours and overtime payment**

For Belgium we do not have detailed information on real working hours and assume that practically all farmers comply with the law. Thus, working time in the asparagus sector does not exceed 11 hours/day and 50 hours/week for seasonal workers. The value for the indicator is set at 99%. In Peru, workers in our sample work for an average of 8.27 hours/day and 49.27 hours/week in either field or processing plant activities. The Peruvian law foresees that employees must not exceed 48 working hours/week, without receiving overtime compensation. While this translates into a maximum of 8 hours per day in the ‘Common Labour Regime - Law 728’, under the ‘Agricultural Sector Promotion Law 27360’ weekly working time can be accumulated and overtime is only paid when it exceeds the average working time of 48 hours/week. In 77% of all employment cases in our sample, working hours comply with the 8 hours/day. In 69% of all cases they comply with the average of 48 hours/week.
Decent working conditions
No detailed data about working conditions in the Belgian asparagus sector are available. In Peru, data come from the worker survey. The indicator is subdivided into three subcategories indicating the percentage of the workforce at the field and processing level with access to (a) clean drinking water, (b) toilet and (c) shower facilities.

Revenue distribution
Average annual producer prices for asparagus are provided until 2013 by Faostat (2015) and supermarket prices for fresh asparagus have been obtained from a Belgian retail company. For Peruvian asparagus the average supermarket price per kg over 2 years, i.e. from December 2012 until November 2014 is based on average prices for a 200g box of green asparagus tips (3.84 EUR) and a 500g-bunch of white asparagus (3.72 EUR). The unweighted average price per kg is thus (5*3.84+2*3.72)/2=13.32 EUR/kg which we convert to USD using the average annual exchange rate of 2013. This yields 17.69 USD/kg. For Belgian fresh white asparagus, the average prices received for a box of 500g during the season (April until June) has been 4.425 EUR/ box in 2013 and 3.328 EUR/ box in 2014. The average per kg is thus 7.75 EUR/kg or 10.29 USD/kg.

Belgium: (3.19 USD/kg/10.29 USD/kg)*100=31%
Peru: (1.13 USD/kg/17.69 USD/kg)*100=6.39%

Labels and certification
The percentage of companies that have at least one certification has been estimated by Schuster and Maertens (2015) for Peruvian asparagus agro-export companies. For the year 2011, this has been 38% of the companies, out of which 35% are certified to at least one production standard (mostly GlobalGAP) and 25% to at least one processing standard (mostly BRC6). Since most of the largest companies are however certified, 81% of all exported asparagus from Peru is certified in 2011. For Belgium we assume that 99% of farmers are certified as all farmers that are members of an auction (i.e., most asparagus farmers) have to be Vegaplan, GlobalGAP and Flandria certified.

## Discussion

### 6.1 Contribution to economic development

There are several channels through which asparagus production can foster economic development. We are considering two channels: First, participation in the value chain through farming activities and second, through employment in the labour market. The absolute development impact through participation of farmers and workers in the asparagus value chain is much larger in Peru compared to the small Belgian sector. Whereas in Peru, around 3,200 farms have been involved in asparagus production in 2012, only 157 farmers cultivated the crop in Belgium. Similarly, we estimate that the Belgian asparagus sector created 509 full-time equivalent jobs per year whereas in Peru 71,796 jobs were created.

For comparing the relative economic impact of asparagus production we use two indicators; the farm revenue per unit of land use and per agricultural worker. First, economic land productivity measured in international USD is lower in Peru (23,084 int’l USD/ha) compared to Belgium (23,735 int’l USD/ha) indicating that Belgian asparagus farmers generate nearly 700 USD more per ha than their Peruvian counterparts. However, asparagus cultivation in Peru generally provides a higher added value per ha than the production of crops for the national market (Schwarz et al. mimeo). Second, economic labour productivity measured in international USD is around 4,400 USD higher in Belgium (15,202 int’l USD/worker) compared to Peru (10,827 int’l USD/worker). Differences in these two indicators may be due to differences in the average producer price received by Belgian and Peruvian farmers which is around 700 international USD/t higher in Belgium than in Peru. The better performance of the Belgian asparagus sector regarding land and labour productivity might change when also considering the cost of production in the two countries. For instance labour costs are more
than three times higher in Belgium, where farm workers are paid around 10 international USD/hour whereas Peruvian workers receive 3 international USD/hour\textsuperscript{7}.

The economic development through labour market effects is assessed through two indicators. First, the number of field and processing plant workers per hectare proxies the employment impact of the sector. We estimate that in Peru, 2.13 full-time equivalent workers are needed per ha of asparagus production and in Belgium 1.5 workers/ha. This can be attributed to the large number of workers needed for post-harvest activities in Peru. Second, the share of migrant workers in the asparagus sector indicates the impact on regional employment creation. In Belgium, nearly all workers come from other countries. In Peru, the regional employment effect is larger as more than half of the workers come from the production area; the other half of the workers come from outside the production regions and migrate to the coastal areas to work in the horticultural sector. One has to be careful when interpreting these results, as employment generation in the asparagus sector is very seasonal, providing work for up to 3 months per year in Belgium and up to 5-6 months per year in Peru.

In summary we find that asparagus production has a higher impact on employment creation in Peru but generates less revenue per ha and per worker. This can be linked to the policy environment in Peru which has been created to increase the competitiveness of the non-traditional export sector.

6.2 Resource use

The attribute resource use is represented by six indicators. We find a huge difference in GHG emissions per kg of asparagus that can be attributed to the distance and the mode of transportation. Whereas Belgian asparagus is transported within Belgium by truck which emits 0.03 CO\textsubscript{2}-eq./kg, Peruvian asparagus travels around 10,000 km by plane and emits 11.12 CO\textsubscript{2}-eq./kg. This result is comparable to the findings of Stoessel et al. (2012) who have calculated carbon emissions of asparagus supply chains from cradle-to-gate. When comparing land and labour productivity, the Peruvian supply chain has much higher yields (11.38 t/ha compared to 7.65 t/ha in Belgium). This can be due to the fact that in Peru up to two harvests are possible per year which increases the physical land productivity for asparagus production. Despite differences in yields, the difference in physical labour productivity between the two countries is very small, between 5.34 and 5.5 tonnes per full-time equivalent worker. This is related to the considerably higher number of workers per ha in Peru which compensates for the yield advantage. Regarding the use of water resources asparagus cultivation in Peru

\textsuperscript{7} Calculations based on average hourly wages from farm surveys (8.5 EUR in Belgium and 4.64 PEN in Peru).
requires much more water than production in Belgium due to differences in climate. In Peru, asparagus cultivation takes place in desert areas with very little rainfall. The difference in consumptive water use per tonne of asparagus amounts to nearly 250 m³ between the two countries. Bearing in mind the water problems in the Peruvian production areas and the relatively high water needs of asparagus, asparagus cultivation is not beneficial from an environmental point of view. Also when considering the economic value that can be generated per unit of water input we find that Peru has both a higher water input and a lower land productivity than Belgium, leading to a lower economic water efficiency of Peruvian asparagus (Schwarz et al. 2015). Per hectare, Peruvian asparagus consumes 12,939 m³ of water, nearly twice the volume of Belgian asparagus (6,801 m³/ha). The last indicator belonging to the attribute resource use compares the irrigation water use for asparagus production to the total water withdrawal of the agricultural sector. In Peru, this amounts to 1.49% whereas in Belgium this only represents 0.12%. This percentage is more than twelve times higher in Peru due to the size of the asparagus sector.

Generally, we find that the Peruvian asparagus sector is more resource-intensive with regards to inputs but also output. More water is used per ha and per ton, but also yields are nearly 50% higher. Moreover, Peruvian asparagus imports are associated with a much higher impact on GHG emissions than local asparagus due to airfreight.

6.3 Labour relations

Regarding labour relations in asparagus production we can compare the performance of the Belgian and Peruvian asparagus chains based on five indicators. In most cases, the Belgian chain performs better, e.g., regarding the payment of the minimum wage, providing legal work contracts and the compliance of working hours with national standards. However, it is important to keep in mind that the indicator values for Belgium are based on assumptions as no detailed data are available on labour relations. When comparing the wage level of asparagus workers to the local living wage, the Peruvian chain performs better. The wage workers receive is nearly twice as high as the local living wage whereas in Belgium, the wage is only slightly above the living wage. By interpreting these data, it is important to consider that in Peru, employment in the horticultural export sector is unstable and workers generally do not work all year round (6.7 months/year (Schuster and Maertens 2016)). Workers are possibly unemployed outside the main production season, as employment alternatives to the agroindustry are rare in the main agricultural export regions. When looking at the total salary a person received from the agro-industrial employment in one year, the number of employed
people per household (1.92 on average; worker survey 2013/2014) and the total household size (4.3 household members on average; worker survey 2013/2014), we find that 28% of the sampled households would fall below the poverty line of 118 USD/ person/month (Peruvian statistics institute’s estimation for the coastal area in 2013 – INEI) and 56% below the living wage line of 159 USD/ person/month (wageindicator.org) if they were only relying on their agro-industrial employment. Finally, despite the large number of employees and the relatively high formality of the sector, in both chains, the percentage of workers who are members of a labour union is extremely low indicating that workers are poorly organized. This is mainly due to the fact that there are hardly any permanent workers in asparagus production which makes it difficult to organize, as well as to a historical discredit of labour unions in Peru.8

6.4 Distribution of added value

For assessing the distribution of added value we have calculated an indicator called revenue distribution. On average a Peruvian farmer only receives around 6% of the price the consumer pays for fresh asparagus whereas a Belgian farmer receives 31%, nearly 5 times more. Thus, although the average supermarket price of Peruvian asparagus is higher than the price of Belgian asparagus (13.32 EUR/kg vs. 7.75 EUR/kg), Peruvian farmers receive a much lower share than their Belgian counterparts. There are many possible reasons for these differences. First, there may be differences in product attributes and in the type of processing. Peruvian asparagus is mainly green and Belgian asparagus is mostly white. Moreover, Peruvian asparagus is often further processed whereas Belgian asparagus is mainly sold fresh. This can lead to price differences along the production chain and to lower average farm gate prices in Peru. Second, Peruvian producers might sell their produce in much higher quantities than Belgian farmers, leading to a lower price per unit. Third, the global Peruvian asparagus supply chain involves more actors than the Belgian chain and the final sales price needs to be shared between more actors. Lastly, distance and means of transportation differ between the two supply chains, leading to differences in transportation costs. Especially air transportation is expensive; it has been estimated that airfreight costs account for 38% of the final price of fresh asparagus exported from Peru to the United States (Díaz Rios 2007).

6.5 Governance

The attribute governance is represented by two indicators: the percentage of producers or export companies that are certified or have a food label and the percentage of total certified produce. In the Belgian chain we assume that nearly all producers are certified. In Peru,

8 See Schuster and Maertens (2016) for a discussion on worker unions in the Peruvian horticultural export sector
nearly 40 percent of the agro-export companies comply with at least one certification scheme. This percentage is thus much lower in Peru than in the Belgian chain. Yet, since all largest producers and exporters in Peru are usually certified, the gap between Peru and Belgium is considerably smaller when looking at the total volumes that are certified in both countries (respectively 99% and 81%). Over time, the certification to private standards in Peru has been steadily increasing, in terms of the number of certified companies (Schuster and Maertens 2013), as well as the variety of standards (Schuster and Maertens 2016). We expect this trend to continue and Peru to catch up with the Belgian values for these two indicators.

7 Conclusions

In this article we have explored the sustainability of local and global asparagus chains. We have done this by describing and analyzing two supply chains of Belgian and Peruvian asparagus in depth. We have calculated a set of indicators to compare different aspects of the two supply chains covering environmental, economic, and social sustainability dimensions. Our results show that trade-offs occur especially between employment generation and resource use, and between employment generation and economic productivity. Concerning the first trade-off we find that the Peruvian asparagus value chain is more resource intensive than the Belgian chain regarding inputs of labour and water and physical output. More employment and higher yields are generated per ha, but asparagus production in Peru also consumes nearly twice the amount of water through evapotranspiration. This is especially critical against the background of debated labour laws and water related problems in the production regions. In absolute terms, the sector yet plays an important role in the national economy and for employment generation. Concerning the second trade-off we find that the Belgian chain generates more revenue per ha and per worker and Belgian farmers receive a much higher share of the supermarket price compared to their Peruvian counterparts. Thus, the local economic impact per unit of asparagus is higher in Belgium. However, Belgian asparagus can only be supplied during a very short season of around three months whereas Peruvian asparagus is a year-round business.

These trade-offs imply that none of the two asparagus supply chains is utterly superior to the other one when taking different sustainability attributes into account. This challenges the presumption that global food supply chains are generally less sustainable than local chains, as for instance intrinsically present in the concepts of ‘food miles’, ‘think global, eat local’, ‘short food chains’, ‘local food systems’ and ‘local-food movements’. Global food value chains can for example have important development impacts through employment generation.
On the other hand, increasing imports might lead to the outsourcing of environmental problems, as for instance the water problems in the Peruvian case. These trade-offs are case-specific and make it very difficult for consumers to make deliberate and well-informed decisions on food purchases. One solution to this dilemma could be more complete food labels, including information on several sustainability dimensions, as suggested by Vlaeminck et al. (2014). Further research on the capability of labels to provide comprehensive sustainability information – e.g. based on the indicators developed and used in this study – to consumers, and the costs involved in such a strategy is required.

The multi-method approach to cross-dimensional sustainability assessment applied in this study has proven valuable for comparing two greatly differing supply chains and to identify trade-offs. Further research could explore multi-criteria approaches based on the participatory selection and weighting of sustainability attributes and indicators. We acknowledge that most of the indicators used in this study focus on the agricultural production stage and do not capture effects along the whole supply chain. This is mainly due to data availability but also reflects that the largest environmental and social impacts are linked to farm and processing activities. Another limitation of the study is that we had to make many assumptions for the Belgian case study. There is very little data available on the asparagus sector, especially on issues related to labour relations. We have, however, based our assumptions on expert interviews and trust that they are good approximations.
