### Abstract

This paper demonstrates the sensitivity of the linear programming approach in the estimation of productivity measures in the primal framework using Malmquist productivity index and Malmquist total factor productivity index models. Specifically, the sensitivity of productivity measure to the number of constraints (level of dis-aggregation) and imposition of returns to scale constraints of linear programing is evaluated. Further, the shadow or dual values are recovered from the linear program and compared to the market prices used in the ideal Fisher index approach to illustrate sensitivity. Empirical application to U.S. state-level time series data from 1960-2004 reveal productivity change decreases with increases in the number of constraints. Further, the input and output shadow or dual values are skewed, leading to the difference in the productivity measures due to aggregation.

### **Aggregation Issues in the Estimation** of Linear Programming Productivity Measures

### Introduction

The linear programming (LP) approach has gained popularity since the early 1990s due to its ability to impose little apriori functional form, handle multiple outputs-inputs without necessitating the use of price data, and accommodate weak and strong disposability assumptions. However, the LP approach, due to its piecewise linear approximation of the technology or theoretical frontier, is conditioned by the number of decision making units (DMU) and the number of constraints (in our case the level of input and output aggregation) in the model. The sensitivity of LP efficiency measures due to output and input aggregation has been established (Thomas and Tauer, 1994; Hanchar and Tauer, 1995; and Shaik, 2007) and referred to as the "curse of dimensionality" problem (see e.g. Thanassoulis et al. 2008: 320). Due to the "curse of dimensionality" problem associated with an increase in the number of constraints (or level of disaggregation), leads to an increase or decrease in the number of reference points resulting in a decrease or increase in the efficiency and productivity measures.

These aggregation issues have been addressed in the literature (Blackorby and Russell, 1999; Färe and Zelenyuk, 2003; and Simar and Zelenyuk, 2003) with the use of dual input, output prices. However, explaining the aggregation issue in the primal framework without the explicit or implicit use of dual or shadow price is challenging.

This paper addresses the "curse of dimensionality" issue by demonstrating that the problem may be due to the shadow or dual values recovered from the constraints of the LP approach. The dual values of the LP constraints should reflect technology and economic behavior of individual DMUs (or states in this case). Theoretically (Caves, Christensen and Diewert, 1982a and 1982b), the computation of productivity measures involves the use of market prices in the case of the ideal Fisher index approach, marginal product in the case of the parametric approach, and shadow or dual values in the case of LP approach. We also demonstrate the shadow or dual values recovered from the LP constraints depend on how the return to scale constraint is imposed in the estimation of the LP productivity measures. The input-based Malmquist productivity index (IMP) or output-based Malmquist productivity index (OMP) imposes a constant returns to scale (CRS) or variable returns to scale (VRS) simultaneous in the input and output constraints (see Färe et al, 1994; Färe et al, 1998; and Grifell-Tatje and Lovell, 1995). In contrast, the Malmquist total factor productivity (MTFP) index model (see Bjurek, 1996) imposes constant returns to scale independently in input and output constraints. Other advantages of the MTFP index (a Hicks-Moorsteen type index) over the standard Malmquist productivity index is that it always has a TFP interpretation and that under weak assumptions of VRS and strong disposability of inputs and outputs it is not unbounded. One can see the TFP discussion in Grifell-Tatjé and Lovell (1995) and in Bjurek (1996), and the issues of infeasibilities and unboundedness in Bjurek (1996).

Specifically, this research demonstrates the sensitivity of the LP approach by comparing the estimated productivity measures and the shadow or dual values<sup>1</sup> (relative to the market prices of the ideal Fisher index approach) of the constraints of the LP model estimated at various levels of aggregation. The following section presents the time-series linear programming OMP, IMP and MTFP index methods. In the third section, a brief description of the U.S. state-level time series data from 1960-2004 is presented. Empirical application and the results along with the performance of methods are presented in section four followed by conclusions.

### **Linear Programming Approach**

For the nonparametric programming approach, technology that transforms input vector  $x_t = (x_{1t}, x_{2t}, ..., x_{it})$  into output vector  $y_t = (y_{1t}, y_{2t}, ..., y_{jt})$  for each DMU k = 1, 2, ..., K(48) over time t = 1(1960), 2, ..., T(2004) can be represented by the output set:

(1) 
$$P(x_t^k) = \{ y_t^k : x_t^k \text{ can produce } y_t^k \}$$

or input set:

(2) 
$$L(y_t^k) = \{x_t^k : y_t^k \text{ is produced by } x_t^k\}$$

and follows the properties of strong disposability of outputs and inputs, and constant returns to scale (CRS) or variable returns to scale (VRS) as in Färe et al, 1994; Färe et al,1998; and Grifell-Tatje and Lovell, 1995.

In a given year, t, the concept of the output set can be represented by the output distance function for k decision-making unit, as:

(3) 
$$OD_t(x_t^k, y_t^k)^{-1} = \max \theta : \theta y_t^k \in P(x_t^k)$$

or the concept of input set can be represented by input distance function for k decision making unit as:

(4) 
$$ID_t^k(y_t^k, x_t^k)^{-1} = \min \lambda: \lambda x_t^k \in L(y_t^k)$$

Time-series Output and Input-based Malmquist Productivity

Following Shaik, 1998 and Shaik et al., 2002 in a time-series observations on a single economic unit (such as the U.S.), an IMP in year *t* relative to the final year *T* can be represented as follows. Consider the multiple of year *t* output that is revealed to be possible relative to the set of all observations including year *T*, using the year *t* bundle of inputs. If outputs could be

<sup>&</sup>lt;sup>1</sup> Other relative issues, slack and disposability are important but beyond the scope of the paper. We also will not be dealing with non-marketable goods or assume weak disposability in estimating productivity measures.

doubled (the multiple is 2.0), then the productivity at time t is the inverse of this multiple, or 0.5. This concept can be represented by an output or input distance function evaluated for any year t using reference production possibilities set T as:

$$(5a) OD(x_t, y_t)^{-1} = \max_{\theta, z} \theta \qquad (5b) ID(y_t, x_t)^{-1} = \min_{\lambda, z} \lambda$$

$$s.t. \quad \theta y_{j,t} \le zY_j \qquad s.t. \quad y_{j,t} \le zY_j$$

$$zX_i \le x_{i,t} \qquad \lambda x_{i,t} \ge zX_i$$

$$z \ge 0 \qquad z \ge 0$$

where  $Y_j = (y_j^1, y_j^1, \dots, y_j^T)$  and  $X = (x_i^1, x_i^2, \dots, x_i^T)$ , the intensity variables  $z \ge 0$  (z = 0) identifies the CRS (VRS) boundaries of the reference set.

The *OMP* measure for a single economic unit, between two time-periods t and t+1, given technology, is defined as:

(6) 
$$OMP_t^{t+1} = \frac{OD(x_{t+1}, y_{t+1})}{OD(x_t, y_t)}$$

and IMP measure for a single economic unit, between two time-periods t and t+1, given technology, is defined as:

(7) 
$$IMP_{t}^{t+1} = \frac{ID(y_{t+1}, x_{t+1})}{ID(y_{t}, x_{t})}$$

Time-series Malmquist Total Factor Productivity

Following Bjurek (1996), an alternative to the time-series OMP or IMP index, time-series MTFP Malmquist total factor productivity (MTFP), is the ratio of Malmquist output index (MO) and Malmquist input index (MI). The MO index measures the scalar change in outputs assuming the inputs are constant over time. Here inputs are constant, meaning that input usage does not change. Hence this would reflect the computation of an ideal Fisher output quantity index. Similarly the MI index measures the scalar decrease in inputs assuming the outputs are constant over time. Here outputs are constant, meaning that output produced does not change. Hence this would reflect the computation of an ideal Fisher input quantity index.

This concept of MO and MI can be represented by the modifying equation (5a and 5b) output and input distance functions evaluated for any year t for a single firm employing a reference production possibility set T

(8a) 
$$OD(x_t (= constant) y_t)^{-1} = \max_{\theta, z} \theta$$
 (8b)  $ID(y_t (= constant) x_t)^{-1} = \min_{\lambda, z} \lambda$   
 $s.t. \quad \theta y_{j,t} \le zY_j$   $s.t. \quad \lambda x_{i,t} \ge zX_i$   $y_{j,t} \le zY_j$   $z \ge 0$   $z \ge 0$   $y = constant$ 

where  $Y_i = (y_i^1, y_i^1, \dots, y_i^T)$  and  $X = (x_i^1, x_i^2, \dots, x_i^T)$ , the intensity variables  $z \ge 0$  (z = 0) identifies the constant (variable) return to scale boundaries of the reference set.

The MTFP for a single economic unit maintaining the index productivity notion is represented as:

(9) 
$$MTFP = \frac{MO}{MI} = \frac{OD(x_{t+1}(=constant), y_{t+1})}{OD(x_t(=constant), y_t)} * \frac{ID(y_t(=constant), x_t)}{ID(y_{t+1}(=constant), x_{t+1})}$$

To illustrate the sensitivity of the nonparametric program approach to the level of commodity aggregation, we compare the share-weights recovered from the dual values implicit in the linear programming constraints. In the programming approach, the share-weights are recovered from the dual values (dv) of the output (input) constraints defined in equation 5a (equation 5b) as well as the dv recovered from the output (input) constraints in equation 8a of MO (equation 8b of MI) of MTFP.

The dv of the linear programming input (equations 5b and 8b) and output (equations 5a and 8a) constraints are normalized to one, and are equivalent to the share-weights. Following Shaik (1998) and Shaik et al. (2002) the nonparametric implicit output and input share-weights in terms of the dv are represented as:

$$(13) RS_j = \frac{dv_j}{\sum_i dv_j}$$

x = constant

$$(14) CS_i = \frac{dv_i}{\sum_i dv_i}$$

where RS; and CS; are the implicit output and input share-weights recovered from the linear programming constraint and dv are the dual values obtained from the output and input linear programming constraints.

### **U.S. Agriculture Data**

The U.S. Department of Agriculture's Economic Research Service (ERS) constructs and publishes the state and aggregate production accounts for the farm sector.<sup>2</sup> The features of the state and national production accounts are consistent with the gross output model of production and are well documented in Ball et al. (1999). Output is defined as gross production leaving the farm, as opposed to real value added (quantity index, base 1960=100). All inputs are quantity index with 1960=100. Finally, quantity indexes are constructed as the weighted sum of the rate of growth of the components, where the weights are the respective value (output or input) shares. As such, the indexes measure the annual rates of change in the output or input aggregate.

The state-wise annual growth rate of the variables' employed in the estimation of productivity for the period 1960-2004 is presented in Table 1. Annual growth rate is defined as  $\left[(x_{t+1}/x_t)^{1/n}-1\right]*100$  where x is input or output variable and n is the number of years in the time period. Within outputs, the average annual growth rate across all the states for crops is 1.464 followed by livestock with 0.942 and other farm revenue with 0.715. In the input category, capital (-0.339), land (-0.881) and labor (-2.187) had a negative average annual growth rate across all the states compared to positive average annual growth rate of energy (0.444), material (0.7) and chemicals (2.014). The productivity computed based on the average annual growth rate of output (1.315) and input (-0.342) leads to average annual productivity growth rate of 2.136.

### **Empirical Application and Results**

To illustrate the sensitivity of the LP to the level of aggregation, equation 5a (output based Malmquist productivity measures, OMP) and equation 8a and 8b (Malmquist total factor productivity measures, MTFP) are estimated for various levels of commodity and input aggregations using state-level data from 1960-2004. First, productivity measures estimated by alternative models are compared to the ideal Fisher index productivity measure. Second, the shadow or dual values of the LP constraints for disaggregate Malmquist productivity index and the Malmquist total factor productivity index, are compared to the market prices used in the Fisher index.

The state-wise annual productivity growth rate<sup>3</sup> estimated for the period 1960-2004 using OMP and MTFP index time series models for various levels of aggregation are presented in Table 2. Specifically, two<sup>4</sup> levels of dis-aggregation were considered: (1) single output and single input (SOSI) model with an aggregate input and aggregate output; and (2) multiple output and multiple input (MOMI) model with 6 inputs and 3 outputs.

For aggregate or SOSI technology, the OMP estimated an annual growth rate of 2.136 for CRS (1.55 for VRS) that is identical (different) to the ideal Fisher index measure. Since the SOI

<sup>&</sup>lt;sup>2</sup> The data are available at the USDA/ERS website http://www.ers.usda.gov/data/agproductivity/.

<sup>&</sup>lt;sup>3</sup> The detailed annual productivity measures computed can be obtained from the author.

<sup>&</sup>lt;sup>4</sup> Results from other levels of disaggregation: (1) single output and multiple input (SOMI) model with an aggregate output and 6 inputs; and (2) multiple output and single input (MOSI) model with an aggregate input and 3 outputs are available from the author.

or aggregate technology is immune to the divergences in productivity, measures such as share-weights are not used in the estimation process of the LP model. In contrast, the MTFP index for the SOSI model estimated an annual productivity growth rate of 1.9127 for CRS and VRS technology. Even though MTFP index has a TFP interpretation and it is not unbounded that under weak assumptions of VRS and strong disposability of inputs and outputs the productivity measures are expected to be identical given equation (9) was estimated under constant input (output) for MO (MI). This is different from the ideal Fisher index productivity measure of 2.136 (Table 2). The annual productivity measures estimated by the ideal Fisher productivity index, OMP index, and MTFP index for SOSI are graphically presented by state (state FIPS<sup>5</sup> code) in Figure 1.

Results for disaggregate or multiple output and multiple input (MOMI) model with 6 inputs and 3 outputs are also presented in Table 2. The OMP index estimated an annual productivity growth rate of 1.0244 for CRS (1.0074 for VRS), while the MTFP estimated an annual growth rate of 1.3612 for CRS and VRS technology. These annual productivity growth rates for the MOMI models were different from ideal Fisher index measure. Further, the estimated annual productivity growth rate from the MOMI model is different from the SOSI model. Figure 2 presents the annual productivity measures estimated by the ideal Fisher productivity index, OMP index, and MTFP index for the MOMI models by state (state FIPS code).

This difference in the annual productivity growth rates due to "curse of dimensionality" problem is consistent with the efficiency (Hanchar and Tauer, 1995; Tauer, 2001; and Thomas and Tauer, 1994) measures. In a productivity framework it is obvious that the "curse of dimensionality" problem leads to decreased productivity growth measures and the results in Table 2 support the argument. In addition, results also show the sensitivity of the use of CRS and VRS technology due to the composition of the theoretical frontier (or envelope).

OMP is out-based Malmquist productivity index, MTFP is the Malmquist total factor productivity, CRS is constant returns to scale, VRS is variable returns to scale, MOMI is multiple output and input and SOSI is single output and input.

Next, we identify the "curse of dimensionality" problem in reference to the shadow or dual values of the LP constraints. We also demonstrate the weights or shadow prices recovered depends on how the CRS or VRS constraint is imposed in the estimation of the OMP and MTFP indexes. To accomplish this objective, we compare the endogenous share-weights recovered from the dual values of the linear programming constraints of the OMP and MTFP programming method for various levels of commodity and input aggregation. Also, we compare the endogenous share-weights recovered from the programming approach to the exogenous shareweights of the ideal Fisher index approach from 1960-2004. The average input and output shares of the ideal Fisher index approach, the OMP programming approach, and the MTFP programming approach for the disaggregate model are presented in Table 3<sup>6</sup>. Results in Table 3 indicate that the average shadow shares of the OMP and MTFP programming approach are different from the exogenously observed market shares of the ideal Fisher index approach. For example, in the ideal Fisher index approach, the average land, labor, capital, chemicals, energy and materials share are 9%, 27%, 13%, 6%, 4%, and 41%, respectively. Compared to the ideal Fisher index approach, the average shadow or dual values input shares computed for OMP programming approach with VRS technology are 30%, 16%, 20%, 9%, 12%, and 13% respectively for land, labor, capital, chemicals, energy and materials. Similar average shadow or dual values input shares with CRS technology are 15%, 24%, 9%, 15%, 12%, and 26% respectively for land, labor, capital, chemicals, energy and materials. This is different from the shares used in the ideal Fisher index approach and recovered from the LP approach with VRS technology.

Similarly, the average shadow or dual values output shares computed from OMP programming approach with VRS (CRS) are 28%, 50% and 23% (28%, 54% and 18%) respectively for crops, livestock and other farm revenue. However, they are different from the output shares used in the ideal Fisher index. In the ideal Fisher index approach, crop and livestock had a share of 49% and 46%, respectively, with the remaining attributed to other farm revenue.

In contrast, the output and input shares recovered by the MTFP programming approach under CRS and VRS technology were identical. These shares were different from the shares used in the ideal Fisher index approach and recovered from the OMP programming approach with VRS and CRS technology.

One of the main reasons for the difference in the productivity measures across models is the use of share-weights to form the technology or theoretical fr

ontier (envelope). Unlike the ideal Fisher index approach, the average share-weights or shadow prices used in programming approach are driven by the number of input and output constraints used in the estimation. For example, with a 6 inputs-3 outputs disaggregation model, the OMP or MTFP linear programming approach allocates maximum share-weight on a single

<sup>6</sup> The annual shadow or dual prices recovered from the linear program approach can be obtained from the author.

<sup>&</sup>lt;sup>7</sup> Due to the piecewise linear approximation of the programming approach for some inputs or outputs, the shares approximated from the linear programming constraints might attach zero or 100 percent weight. The shares present in the Table 3 are averaged across the whole time period.

input with a huge positive rate-of-change resulting in a very low productivity measure. Alternatively, if the OMP or MTFP linear programming approach allocates maximum shareweight on a single input with a lowest rate-of-change, then the productivity measures would be very high.

### Conclusion

This paper examines the sensitivity of nonparametric programming productivity measures to the choice of commodity/input aggregation and imposition of CRS/VRS technology compared to the traditional ideal Fisher index approach using U.S. state-level data from 1960-2004. The importance of share-weights in explaining the sensitivity of the nonparametric productivity measures is illustrated by comparing the implicit shadow shares recovered from the dual values of the linear programming constraints in the OMP and MTFP programming methods to the observed shares of the ideal Fisher index.

The analyses at the U.S. state level indicates productivity measures estimated from the OMP programming approach with CRS technology is identical to the ideal Fisher index productivity measures for aggregate (single output and single input) technology. Divergence in productivity measures is observed not only due to choice of method –OMP and MTFP methods and various levels of commodity and input aggregation, but also between CRS and VRS technology. Due to the piecewise linear approximation of the nonparametric programming approach, the shadow share-weights are skewed leading to the difference in the productivity measures across methods, models and various levels of commodity aggregation.

The importance of the results reported in this paper will depend upon the researcher's objectives and the availability of data. If prices are available utilizing the price information (as share-weights) in the computation of productivity measures, either by the index and or linear programming approach will provide similar productivity measures. However, for the unpriced, non-market goods, like environmental pollution, the unavailability of price information would motivate researchers to apply the programming approach to estimate the productivity measures as well as to recover the shadow prices.
