# International Interlinkages of Biofuel Prices: The Role of Biofuel Policies<sup>1</sup>

## Abstract

Kliauga, de Gorter, and Just (2008) and de Gorter, Drabik, and Just (2010) argue that the United States and the European Union establish the world ethanol and biodiesel prices, respectively. We test these theories using a cointegration analysis and the Vector Error Correction (VEC) model. Weekly price series are analyzed for the major global biofuel producers (European Union, United States, and Brazil) for the period 2002 – 2010. Biofuel policies in both the United States and Brazil appear to play a role in determining the ethanol prices in other countries, thus only partially confirming the previous findings for the U.S. price leadership in the literature. For biodiesel, our results demonstrate that the EU tax exemption and mandate impact the world biodiesel price, thus confirming the European Union's price leadership.

**Key words:** biofuels, biofuel policies, price leadership, VEC

**JEL:** C32, Q16, Q17, Q47

## 1. Introduction

Understanding how ethanol and biodiesel prices are established and linked internationally is critical for analyzing the worldwide biofuel price response to biofuel policies or to exogenous shocks, such as oil price fluctuations. The recent increase in the volatility of global commodity prices has attracted a lot of policy makers' attention. Governments from around the world have introduced various measures to react to this structural change in the commodity markets. In this respect, the biofuel sector plays a prominent role as it is perceived to be the key factor driving recent price developments. Understanding the interlinkages among the biofuel prices also allows to evaluate the efficiency of the biofuel policies and more specifically, to study the impact that biofuel policies have on the changes of commodity prices.

There is a growing body of literature on the economics of biofuel policies and the interlinkages of commodity prices (e.g., Balcombe and Rapsomanikis 2007; Babcock 2008; Xiaodong and Hayes 2009; de Gorter and Just 2009, 2010; Zhang et al. 2009, 2010; de Gorter, Drabik, and Just 2010; Ciaian and Kancs 2011). Theoretical studies show that the biofuel policies are the key drivers of biofuel prices. Given the current policies, according to Kliaugas, de Gorter, and Just (2008) and de Gorter, Drabik, and Just (2010) the world market price of a biofuel is either (i) linked to the fossil fuel price adjusted by a tax credit (or tax exemption) in the country with a combination of the highest fossil fuel price and the lowest net tax or (ii) it is determined by a binding mandate if the biofuel price in the country is higher than under the case (i). This theory implies two empirically testable price relationships. First, if the tax credit (or tax exemption) drives the biofuel prices, then one would observe that the fossil fuel (gasoline, diesel) price in the price leading country determines the biofuel prices in other countries. Second, if the biofuel mandate determines the biofuel prices, then the biofuel price in the price leading country should determine the biofuel prices in other countries. Kliaugas, de Gorter, and Just (2008) showed that the world ethanol price has historically been determined in the United States. Similarly, de Gorter, Drabik, and Just (2010) demonstrated that the European Union by

its biofuel policy has determined the world biodiesel price. The main shortcoming of those two studies is their empirical approach – they do not provide a rigorous econometric test of their theory.

The objective of this paper is to rectify their empirical approach and formally test the validity of their theoretical conclusions. Notably, we examine the price leadership among the major biofuel players – the European Union (proxied by Germany), the United States, and Brazil – representing more than 90 percent of the world biofuel market. Price relationships in different commodity markets were extensively studied in the literature. Regarding energy markets, several studies analyze price interdependencies at the global level as well as among different types of energy markets: the European natural gas market has been analyzed by Asche, et al. (2001); the European, Japanese, and North American natural gas markets by Siliverstovs, et al. (2005); the U.S. natural gas market by Cuddington and Wang (2006); the U.S. retail gasoline market by Paul, et al. (2001); the U.S. petroleum market by Asche, et al. (2003); and U.S. natural gas, fuel oil, and electric power markets by Serletis and Herbert (1999). However, to our knowledge, there are no studies focusing on biofuels and fossil fuel markets.

The remainder of the paper is organized as follows. In Section 2, we briefly describe biofuel policies in the countries analyzed. In Section 3, we formulate the tested hypotheses. Section 4 describes the data used and Section 5 presents the cointegration techniques followed. Empirical results are presented in Section 6. Finally, Section 7 provides some concluding remarks.

## **2. Biofuel Policies**

There is a variety of policies that can directly or indirectly impact either biofuel production or consumption. The first category includes blenders' tax credits, tax exemptions, mandates, production quotas, and production subsidies targeted on biofuel production, while the second group consists of policies such as import tariffs, production subsidies on biofuel feedstocks, or research and development subsidies. Given their importance in terms of the budgetary spending

and frequency of their use in many countries, we focus only on the first three policies listed (i.e., blenders' tax credits, tax exemptions, and mandates). Furthermore, we only describe the policies used in the countries covered in the paper: the United States, the European Union, and Brazil.

Under a blender's tax credit, the blender receives a subsidy per gallon of biofuel blended with a fossil fuel (i.e., gasoline or diesel, depending on the biofuel). This policy is used in the United States where, currently, the blender's tax credit for ethanol is 52 cents per gallon of which 45 cents are granted from federal funds and the rest is the average state tax credit. Up to January 2010, biodiesel blenders enjoyed a tax credit of \$1 per gallon of biodiesel blended with regular diesel.

A tax exemption represents a reduction in the fuel excise tax collected at the pump level in the European Union and Brazil. The economic impacts of a blender's tax credit and tax exemption are identical in a closed economy – both constitute a biofuel consumption subsidy, but differ substantially in an open economy framework.<sup>2</sup> The level of the tax exemption varies among the EU countries and between biofuels, but it is on a decline as governments are essentially forgoing considerable fiscal revenues from fuel taxes with this policy. For example, a tax exemption on biodiesel in Germany was reduced from 0.47 Euro per liter to 0.29 Euro per liter between 2005 and 2009. For Brazil, Kliaugas, de Gorter, and Just (2008) report the average (consumption weighted) tax exemption of 0.67 dollars per liter which is approximately 2.7 times the U.S. tax credit.

A mandate is another widely used biofuel policy. In most cases it is combined with either a blender's tax credit or a tax exemption. A biofuel mandate is used in two forms: a consumption mandate (e.g., in the United States) or a blend mandate (e.g., in the European Union, where it is termed a 'target'). While the former establishes that a fixed amount of biofuel be blended with a fossil fuel, the latter requires that a fuel mix contain a certain percentage of a

---

<sup>2</sup> The reason is that once the world market price of a biofuel is established by one country (A), a tax credit or a tax exemption in the other country (B) cannot affect it, but acts as a production subsidy in the case of a tax credit and fuel consumption subsidy with a tax exemption. (Kliaugas, de Gorter, and Just 2008; de Gorter, Drabik, and Just 2010)

biofuel. For ease of implementation, the U.S. Environmental Protection Agency annually converts the consumption mandate into its blend equivalent based on a prediction of the annual U.S. fuel consumption; for instance, the blend equivalent of the U.S. ethanol consumption mandate has been set to 7.95 percent in 2011 (Reuters 2010). For comparison, a mandatory 10 percent minimum target is set in the European Union for the share of biofuels in transport fuel consumption by 2020 (Directive 2009/28/EC). In Brazil, 25 percent of gasoline fuel consumption has to come from ethanol (known as the E25 fuel).

### 3. The Theory of Biofuel Price Formation

Theoretical studies show that biofuel policies are the key factor determining the biofuel price. For example, de Gorter and Just (2009, 2010) developed a model that explains the link between the U.S. biofuel policies – the blender’s tax credit or the biofuel mandate – and the biofuel price. In their model, biofuel (ethanol) and fossil fuel (gasoline) are assumed to be perfect substitutes and differ only in their energy content. They conclude that the price of the biofuel is determined either by a tax credit or a binding (consumption or blend) mandate, but never by both at a time.<sup>3</sup>

Consider first a case where a blender’s tax credit on ethanol,  $t_c$ , (or a tax exemption) is the only biofuel policy. Then, based on the model the ethanol market price,  $P_E$ , is directly linked to the gasoline (oil) price,  $P_G$ , and the fuel consumption tax,  $t$ , as follows:

$$P_E = \lambda P_G - (1 - \lambda)t + t_c \quad (1)$$

where the coefficient  $\lambda$  measures miles traveled per gallon of ethanol relative to a gallon of gasoline.<sup>4</sup> An implication of equation (1) is that if the fuel tax and the tax credit do not change over time (as it has been the case in all countries included in our study for at least some time), then the volatility in the world oil price should be transmitted into the ethanol market price, provided that the blender’s tax credit is binding.

---

<sup>3</sup> A biofuel policy is said to be binding if it is determining the biofuel market price. So, for example, even if annual ethanol consumption is below the level dictated by a consumption mandate, the ethanol price can still be determined by the mandate most of the year. For details on this see de Gorter and Just (2010).

<sup>4</sup> For corn ethanol,  $\lambda \approx 0.70$ , while for biodiesel it is somewhat higher,  $\lambda \approx 0.89$ .

Alternatively, assume there is only a biofuel mandate that dictates a certain amount of biofuel to be blended. Although the economics of a consumption mandate differs somewhat from that of a blend mandate (see de Gorter and Just 2009, 2010 for details), the common outcome of the two policies is that, unlike with a blender's tax credit, the biofuel price is not directly linked to the gasoline price: the link is completely severed with a consumption mandate (because the biofuel price is determined by the intersection of the ethanol supply curve and a fixed mandate level) and it is partially severed with a blend mandate insofar as a change in the gasoline price impacts the fuel demand. The intuition behind this result is that the biofuel price is more determined by the biofuel supply than by the gasoline price for a given mandate constraint. In the case of a blend mandate, only with an inelastic biofuel supply will the price of biofuels be strongly linked to a gasoline price (see Appendix).

Finally, suppose (as it is usually the case in reality) that a blender's tax credit (a tax exemption) is combined with a biofuel mandate. For a mandate to bind, the biofuel price premium (i.e., the difference between the ethanol market price with a policy and the gasoline market price in the absence of a biofuel policy) due to a mandate has to be greater than the amount of a tax credit – otherwise the relationship (1) holds.

So far, we have described the biofuel market price formation in a closed economy. There is, however, trade in biofuels and so a question arises as to how the world price of biofuels is established – the question of interest in this paper. Based on the theory above, Kliaugas, de Gorter, and Just (2008) and de Gorter, Drabik, and Just (2010) argue that only one country's policy and market situation determines the world biofuel price and therefore either of the following situations (but never both) holds:

- (i) The world biofuel market price is determined by the gasoline (diesel) price adjusted by a miles-per-gallon coefficient and a tax credit (or tax exemption) in the country with a combination of the highest consumer price paid for gasoline (diesel) and the lowest net tax (the combination of the lowest fuel tax and highest biofuel tax credit/tax exemption).

(ii) The world biofuel market price is determined by a binding mandate if the induced biofuel price is higher than under the case (i).

The general implication of the relationships (i) and (ii) is that the impact of biofuel policies (tax exemptions, tax credits, or price premia due to biofuel mandates) on biofuel prices are not additive: the market price of a biofuel is not determined by the sum of each country's tax exemption, tax credit, or a mandate price premium.

Transportation costs and tariffs also affect biofuel prices. However, they do not affect the direction of causation of the price relationships (i) and (ii). The transportation costs and tariffs may only weaken these relationships.<sup>5</sup> For example, if the United States is the price leader for ethanol, then ethanol prices in other countries are likely to decrease by transportation costs and/or tariffs, or may be independent of the U.S. price if the transportation costs and/or tariffs are prohibitive.

Based on the theoretical predictions (i) – (ii), we can establish two empirically testable hypotheses.

**Hypothesis 1:** *If the fossil fuel prices determine biofuel prices at least in the price leading country, then the relationship (i) holds (i.e., the tax credit (or tax exemption) determines biofuel prices).*<sup>6</sup>

Hypothesis 1 says that if a fossil fuel is an important determinant of biofuel prices at least in the price leading country, then the tax credit/tax exemption policy effectively sets the biofuel prices. This is because the net tax policy (on gasoline/diesel and biofuels combined) of the price leading country provides the most favorable biofuel price at the world level which will be followed by other countries. Consider the price relationship derived in equation (1). Totally differentiating equation (1) yields  $dP_E/dP_G = \lambda$  which implies that the relationship between fossil fuel and biofuel prices in the price leading country is linear and is determined only by the

---

<sup>5</sup> In principle, export subsidies may invert the causality of prices summarized in (i) and (ii). However, this type of trade policy is not applied in reality, particularly so by the major world biofuel players.

<sup>6</sup> Given that a tax credit (tax exemption) (and also a fuel tax) tends to be fixed over a longer period, the varying fossil fuel prices in the price leading country determine the biofuel prices in other countries.

conversion coefficient  $\lambda$ . Given that  $\lambda$  is approximately equal to 0.7 for ethanol and 0.89 for biodiesel, the price causation from the fossil fuel to biofuels is expected to be strong if indeed Hypothesis 1 holds. If this hypothesis holds, then the econometric estimations are expected to show that the fossil fuel price determines biofuels in the price leading country, whereas either the fossil fuel or biofuel prices (or both) in the price leading country determine biofuel prices internationally.

**Hypothesis 2:** *If a biofuel price of a country determines biofuel prices in other countries, then the relationship (ii) holds (i.e., the mandate determines biofuel prices).*<sup>7</sup>

Hypothesis 2 says that the mandate implemented in the price setting country determines the world biofuel prices. With a binding mandate, the biofuel prices tend to be isolated from the fossil fuel market. Based on the model by de Gorter and Just (2009), we have estimated the price response of ethanol to changes in the gasoline price in the price setting country (assuming an exogenous gasoline price). According to the results, the price response of ethanol is negative and very small, between -0.1 and -0.01 (Appendix and Table 1); hence, it is relatively immune from the gasoline price. Internationally, the ethanol price of the price leading country will determine ethanol prices in other countries if indeed mandate is the policy which sets the ethanol prices worldwide. In summary, if the Hypothesis 2 holds, we should observe that the relationship between the fossil fuel price and biofuels is statistically not significant or negative in price the setting country and the ethanol (biodiesel) price of the price leader influences ethanol (biodiesel) prices in other countries. The key difference between the two hypotheses is that the first one implies significant interdependencies between biofuel and fossil fuel prices as compared to the second hypothesis which states that the fossil fuel price is not driving biofuel prices because the mandate tends to isolate the biofuel and fossil fuel markets from each other. Note that the hypothesis 2 is a subset of hypothesis 1 and, therefore, cannot be identified if both

---

<sup>7</sup> This follows from the fact that if the mandate determines biofuel price in the price leader country, then the biofuel and fuel markets are isolated from each other. In this case the fossil fuel price will be independent of the biofuel price.

biofuel policies interchangeably determine biofuel prices over the analyzed period. Only if the mandate is a dominant policy, we can identify the effect empirically.

#### **4. Data**

Our data consist of weekly price observations for ethanol and gasoline (January, 2002 to December, 2010) and biodiesel and diesel (June, 2005 to December, 2010) for the European Union, the United States, and Brazil. The EU data are proxied by German ethanol, biodiesel, gasoline, and diesel prices extracted from the Bloomberg database, UFOP (The Union for Promotion of Oil and Protein Plants), and the EU Commission's Oil bulletin (gasoline and diesel), respectively. The U.S. Gulf ethanol and biodiesel prices come from the Bloomberg database, while the U.S. Gulf gasoline and diesel prices are from the U.S. Energy Information Administration. Finally, Brazilian ethanol and gasoline prices are for Sao Paulo (the biggest Brazilian ethanol producing state) and come from the Center for Advanced Studies in Applied Economics and the Brazilian National Agency of Petroleum, Natural Gas, and Biofuels, respectively.

#### **5. Cointegration**

Theoretical findings from the previous section suggest that fuel prices are interdependent. Applying a standard regression approach to these data would violate the exogeneity assumption of a regression equation. A general approach to analyze interdependences between endogenous variables is the Vector Autoregressive (VAR) model where the causality between the current and past values of the variables is examined. The standard requirement for the VAR estimation is stationarity of the time series. However, even if the individual time series are not stationary a combination of two non-stationary time series may be stationary (Engle and Granger, 1987). In this special case, the time series are said to be cointegrated, i.e., there exists a long-run equilibrium relationship between them and a Vector Error Correction (VEC) model (that adds error correction features to the VAR model) can be estimated.

To test for the stationarity of time series, we use two unit root tests: the augmented

Dickey-Fuller (ADF) test and the Phillips-Perron (PP) test. The number of lags of the dependent variable is determined by the Akaike Information Criterion (AIC). If the time series are not stationary, we employ the Johansen's cointegration method to examine the long-term relationship between the price series. This method allows us to test for the cointegration of several time series and does not require them to be of the same order of integration. The number of cointegrating vectors is determined by a lambda max test and a trace test. Both tests use eigenvalues to compute associated test statistics. The null hypothesis of the test statistics is the existence of at most  $r$  cointegrating vectors. We follow the Pantula principle in order to determine whether or not, the deterministic components (time trend and constant term) should be included in the model.

We first perform a bivariate Johansen cointegration test on the pairs of prices. Based on the patterns obtained from the bivariate case, we test for multivariate cointegration. The bivariate case ignores a possible integration of two markets through a third market, i.e., there may exist a long-run cointegration relationship that ties several markets together whereas such a relationship is not found between two markets alone (Harris, 1995)

Then, we estimate a VAR model for cointegrated variables in which we include a mechanism of the error correction model. We use the AIC and the likelihood ratio (LR) tests to determine the number of lags to be included in the VEC model. In the event that the two tests yield different results, we consider each possibility and first follow the AIC. The adequacy of our VEC model is tested by a series of tests: the Lagrange multiplier test for autocorrelation in the residuals; the Jarque-Berra test for normality in residuals; and the stability test of the VEC model estimates.

A possible cointegration relationship between the price series does not automatically imply a causal relationship between them. Causality tests show whether or not a country is the price leader and which countries are price followers (or it can well be the case that none of the countries dominates the others) (Ciaian and Kancs, 2011). If two variables are cointegrated,

causality in at least one direction must exist. This Granger causality can be detected through the VEC model derived from the long run cointegrating vectors. Statistical significance of the differenced explanatory variables provides information about the short run causal relationships between the variables, while the significance of the lagged error correction term explains the long run causal relationships. However, Granger causality detected through F-tests and t-tests of the VEC model may identify the Granger causality only within the sample period. We therefore employ the Variance Decomposition technique to measure the effect of shocks to each price on the current and future values of the own and other prices. We perform a decomposition of the variance associated with each price in the VEC model caused by shocks to the other prices after 1 to 48 weeks. By this, we examine the price relationships summarized in Hypotheses 1 and 2, i.e., which country's prices cause biofuel prices in other countries.

## **6. Empirical Results**

To get a first impression on the strength of prices interdependence, we report the correlation coefficients in Table 2. The correlation analysis confirms a high and positive correlation (0.717) between the ethanol prices in Brazil and Europe. There is also a positive correlation between the EU and U.S. ethanol prices (0.649), as well as between the United States and Brazil (0.614). The correlation between biodiesel prices in the EU and U.S. markets is even stronger (0.969) (Table 3).

However, before making any judgments about the relationship between the prices, we first need to analyze the characteristics of the time series. The use of non-stationary time series could lead to statistically significant results due to a spurious regression. Based on the Dickey-Fuller and Phillips-Perron tests, all time series are non-stationary. We achieved stationarity by taking first differences of the series.

Next, to be able to test for interdependencies between prices, we examined whether there exist a cointegrating vector among fossil fuel and biofuel prices. The results show that gasoline and ethanol prices are cointegrated, except for two price pairs: EU – Brazilian ethanol price, and

EU ethanol – Brazilian gasoline price (Table 4). Both the trace and the likelihood ratio tests reject the absence of cointegration relationship between the EU and U.S. biodiesel prices, and the EU and U.S. diesel prices at a 1 percent significance level. The rest of diesel-biodiesel price series is found not to be cointegrated.

Results of the multivariate Johansen cointegration test indicate that the series under consideration are cointegrated of rank 3 in the case of gasoline and ethanol, and of rank 1 for the biodiesel and diesel prices. The cointegration analysis shows that fossil fuel and biofuel prices are interlinked. However, the cointegration analysis cannot predict the direction of causality between the price series. To identify the causality relationships we estimate the VAR model.

#### *Variance Decomposition*

Based on the VEC results, we perform variance decomposition of the price relationships to examine Hypotheses 1 and 2. The variance decomposition indicates how much the current and future values of biofuel prices can be explained by exogenous shocks in own and other prices. According to the results reported in Table 5, in all three countries ethanol prices are most responsive to their own lagged values, i.e., the own lagged values (own shocks) explain between 50 percent and 99 percent of biofuel price variances. However, the effect decreases over time. The rest of price series (i.e., gasoline prices, non-own ethanol prices) participate individually between 1 percent and 50 percent in the variance of ethanol prices, depending on the country and time horizon considered.

The U.S. ethanol price contributes to the variance of the European ethanol prices after 48 weeks by 11.91 percent. The relative variance in ethanol prices in Europe is then caused by the shocks to the Brazil ethanol prices (9.5 percent) and partially by the shocks to the gasoline market in the three countries (almost 7 percent all combined).

On the other hand, the relative variance in the U.S ethanol prices is resistant to the shocks to the EU ethanol prices (0.12 percent after 48 weeks). The Brazilian ethanol price participates with 13.54 percent in the variance of the U.S. ethanol prices after 48 weeks. The

relative variance in the U.S. ethanol prices caused by the shocks to Brazilian gasoline prices is even stronger, 22.28 percent. The variance decomposition results further indicate that the U.S. ethanol prices also react relatively strongly to the U.S. gasoline prices (11.01 percent after 48 weeks) but their reaction to the EU gasoline price is weak (less than 1.22 percent)

The Brazilian ethanol prices are most responsive (besides own price) to the EU gasoline price (17.01 percent after 48 weeks) and Brazilian gasoline (6.35 percent). The rest of prices determine to a lesser extent the Brazilian ethanol prices.

The results in Table 5 confirm that for ethanol, Hypothesis 1 tends to prevail relative to Hypothesis 2. Both gasoline prices and other countries' ethanol prices co-determine ethanol prices indicating that the tax credit (or tax exemption) policies (Hypothesis 1) and not mandates (Hypothesis 2) are those that effectively set the ethanol prices. Gasoline prices explain 34.51,<sup>8</sup> 6.66 and 25.27 percent of the ethanol price variation in the United States, European Union, and Brazil, respectively. On the other hand, the other countries' ethanol price contributes with 13.66,<sup>9</sup> 21.41, and 2.31 percent to the ethanol price variation in the United States, European Union, and Brazil, respectively. In order for the Hypothesis 2 to hold, the gasoline impact on the ethanol would need to be small. However, both the U.S. and the Brazilian gasoline significantly affect the ethanol price which tends to imply the rejection of the second hypothesis. Note that because the hypothesis 2 is a subset of hypothesis 1, both policies could interchangeably affect biofuel prices, but we cannot identify their separate effects. Given the fact that gasoline price plays an important role in biofuel price formation, the tax policy is likely dominating the mandate.

The U.S. and Brazilian policies appear to determine ethanol prices in other countries. The U.S. ethanol and gasoline contribute to the variance of the EU and Brazil ethanol prices by 14.40<sup>10</sup> and 3.18 percent, respectively. Brazilian ethanol and gasoline prices contribute to the

---

<sup>8</sup> 34.51% = 1.22% EU gasoline + 11.01% USA gasoline + 22.28 Brazil gasoline

<sup>9</sup> 13.66% = 0.12% EU ethanol + 13.54% Brazil ethanol

<sup>10</sup> 14.40% = 11.91% U.S. ethanol + 2.49% U.S. gasoline.

variance of the EU and U.S. ethanol prices by 10.2 percent and 35.82 percent, respectively. The EU plays a minor role in determining ethanol prices in other countries (less than 5 percent) except for the EU gasoline which is an important driver of Brazil ethanol (17.01 percent).

These results partly confirm the prediction of Kliauga, de Gorter, and Just (2008) that the United States is the price leader for ethanol. Contrary to their findings, we find that both the United States and Brazil play a role in global ethanol price formation, but Brazil has a significantly stronger impact on the U.S. ethanol (35.82 percent) than *vice versa* (3.17 percent). However, the mechanism of price determination differs between the two countries. Both the United States and Brazil impact the EU ethanol through the ethanol price. However, the reciprocal effects are different. The United States determines Brazilian ethanol price equally through the ethanol and gasoline prices, whereas Brazil affects the U.S. ethanol mainly through the gasoline price.

With regards to biodiesel, akin to the ethanol, most of the variance in all biodiesel prices can be explained by its own innovations (more than 68 percent) (Table 6). The effect of the shocks to the EU biodiesel price on the current and future values of U.S. biodiesel price is much stronger than *vice versa*. The European biodiesel price contributes to the variance of the U.S. biodiesel prices after 48 weeks by 26.54 percent, while it is only 0.09 percent *vice versa*. The EU biodiesel is significantly affected by the EU diesel price (12.78 percent). Other prices play only a minor role in determining biodiesel prices in the European Union and the United States. These results tend to confirm the Hypothesis 1 and the prediction of de Gorter, Drabik, and Just (2010) that the European Union is the price leader in the world biodiesel market. The causation goes as follows: the EU biodiesel price is determined by the favorable EU tax policy which is confirmed in Table 6 by a significant impact of the EU diesel on the EU biodiesel; further the favorable EU biodiesel price sets the price for US biodiesel given by the high EU – U.S. biodiesel causation effect reported in Table 6.

## **7. Concluding Remarks**

This paper has empirically examined the theoretical findings of Kliaugas, de Gorter, and Just (2008) and de Gorter, Drabik, and Just (2010). These papers show two patterns of the interaction between biofuel policies and biofuel price determination. First, if the tax credit (exemption) is the driver of biofuel prices, then one would observe a price behavior where the fossil fuel determines biofuels in the price leading country, whereas internationally either the fossil fuel, biofuel or both prices in the price leader country determine biofuels worldwide. Second, if the biofuel mandate determines biofuel prices, biofuels tend to be isolated from fossil fuel markets and biofuels (ethanol or biodiesel) in the price leading country determine the world biofuel price.

We find that other gasoline prices explain up to 35 percent of ethanol price variation. On the other hand, the other countries' ethanol price contributes to the ethanol price variation up to 22 percent. Our results imply that the U.S. and Brazilian ethanol policies appear to determine ethanol prices in other countries, but the Brazilian impact is stronger than that of the United States. Our findings partially confirm the prediction of Kliaugas, de Gorter and Just (2008) who argue that the U.S. is the price leader for the ethanol.

For biodiesel, our results demonstrate that the EU tax policy impacts the world biodiesel price (Hypothesis 1) and confirm the prediction of de Gorter, Drabik, and Just (2010) that the EU is the price leader in the world biodiesel market.

## Appendix

To illustrate how biofuel price relationships are affected by a blend mandate, we perform a comparative static exercise for the impact of an exogenous fossil fuel (without loss of generality, we assume gasoline) price change on the biofuel price (ethanol),  $dP_E/dP_G$ , in the price leading country. The derivations are based on the model developed in de Gorter and Just (2009).

The equilibrium conditions in the fuel market with an exogenous gasoline price and a binding blend mandate are given by:

$$\begin{aligned} P_F &= \alpha(P_E - t_c) + (1 - \alpha)P_G \\ S_E(P_E) &= \alpha D_F(P_F) \end{aligned} \quad (A1)$$

where  $P_F$ ,  $P_E$ , and  $P_G$  denote price of fuel (combination of ethanol, and gasoline), ethanol, and gasoline, respectively;  $t_c$  denotes a tax credit;  $\alpha$  denotes a blend mandate (e.g., 10 percent), and  $S_E$  and  $D_F$  denotes ethanol supply and fuel demand functions, respectively.

Totally differentiating system (A1) yields:

$$\begin{aligned} dP_F &= \alpha dP_E + (1 - \alpha)dP_G \\ S_E' dP_E &= \alpha D_F' dP_F \end{aligned} \quad (A2)$$

where  $D_F'$  and  $S_E'$  are the first derivatives of the fuel demand and ethanol supply functions, respectively, with respect to their arguments.

Solving system (A2) for  $dP_E/dP_G$  yields:

$$\frac{dP_E}{dP_G} = \frac{\alpha(1 - \alpha)D_F'}{S_E' - \alpha^2 D_F'} < 0$$

Transformation to the elasticity form yields:

$$\frac{dP_E}{dP_G} = \frac{(1 - \alpha)\eta_{DF}}{\eta_{SE} \frac{P_F}{P_E} - \alpha\eta_{DF}} < 0 \quad (A3)$$

where  $\eta_{DF}$  denotes demand elasticity of fuel and  $\eta_{SE}$  denotes supply elasticity of ethanol.

We extract elasticities from de Gorter and Just (2009) to calibrate the derivative (A3). The results are reported in Table 1.

**Table 1. The Magnitude of  $dP_E/dP_G$  for the United States with a Binding Blend Mandate and an Exogenous Gasoline Price**

Year	Ethanol Share of Fuel Consumption ( $\alpha$ )	Ethanol Supply Elasticity ( $\eta_{SE}$ )	Ethanol price ( $P_E$ )	Gasoline price ( $P_G$ )	Fuel price ( $P_F$ )	$dP_E/dP_G$ (for $\eta_{DF} = -0.10$ )	$dP_E/dP_G$ (for $\eta_{DF} = -0.26$ )	$dP_E/dP_G$ (for $\eta_{DF} = -0.40$ )
