Farm subsidies and agricultural employment:

The education channel

1. INTRODUCTION

The past century has witnessed a major decline in western countries' workforce employed in the agricultural sector. A hundred years ago, almost one out of two persons in North America and Western Europe was employed in agriculture. In 2008, the share of agricultural employment was 3.4% in the EU15 and 1.5% in the US.[1] This decline accelerated in the past decades. Between 1971 and 2009, agricultural employment in the EU15 decreased by 45% to 85%. In Spain for example, the share of agricultural employment dropped from 30% in 1971 to 4% in 2009 (Figure 1).

Figure 1: Evolution of the share of agricultural employment (1971-2009)
Source: Eurostat, ILO

Agricultural activities in the EU15 are traditionally concentrated in family farms, which are usually transmitted from generation to generation.[2] The decline in agricultural employment is largely due to the fact that farmers' children in these countries have been turning more and more to industry or services rather than taking over their parents' farm (Calus et al., 2008). For example, in 2008, only 27% of all Dutch farmers older than 50 indicated that they had a successor and in the Belgian Flanders region, this percentage was even lower (13%) (De Bont and Van Everdingen, 2010; Vlaamse Overheid, 2009).

This decline in agricultural employment is taking place despite the fact that rich economies have introduced considerable farm income support. In the period 2003-2008, the US government spent between USD 12 billion and USD 20 billion per year for supporting farmers (USDA Economic Research Service). In the period 2005-2010, The EU spent more than 50 billion euros per year for supporting farmers through the Common Agricultural Policy. If one takes into account support through market regulations, support to farmers in 2009 was around 87 billion euro (OECD, 2010).

Given the size of the income support directed to farmers, the speed of decline in agricultural employment is puzzling. Intuitively, one would expect subsidies to have a positive impact on agricultural employment. However, empirical evidence suggests that the opposite is happening. The outflow of labor from the agricultural sector has been

---

[1] Timmer (2009) describes the fast structural change in the agricultural sector of the rich economies and how it is propelling their economies to " A World Without Agriculture". He arguments that this process is occurring fast and illustrates this by the following statement "In the United States today there are more lawyers than farmers, more dry cleaning establishments than farmers".

[2] In 2007, 83% of the EU-15 agricultural labor force was concentrated in family farms and in some countries, such as Ireland (99%), Spain (99%) and Italy (96%) virtually all agricultural employment was in family farms. For a detailed overview of the reasons for the dominance of intergenerational farm succession, see Stiglbauer and Weiss (2000).

strongest in the countries which have supported agriculture most heavily. A quick look at OECD data over the period 1987–2007 shows that changes in agricultural income support, captured by producer support estimate (PSE) indicator were negatively correlated with changes in agricultural employment (Figure 2). A similar pattern can be observed at the sub-sector level within agriculture. The most heavily subsidized sub-sectors had the strongest employment decline (Figure 3).

Figure 2: Change in agricultural labour and change in PSE (1987-2007)

Several authors papers have analyzed the impact of subsidies on agricultural employment, but the results are mixed. A first group of studies found no effect of subsidies on agricultural employment (Barkley, 1990; Mishra et al., 2004; Glauben, et al., 2006). A second group of studies found a positive impact of subsidies on agricultural employment (Foltz, 2004; Key and Roberts, 2006; Breustedt and Glauben, 2007; Pietola et al., 2003). A third group of studies found a negative impact of subsidies on agricultural employment (Goetz and Debertin, 1996, 2001; Hoppe and Korbi, 2006; Petrick and Zier, 2010).[4]

This conflicting evidence suggests that the impact farm support programs on agricultural employment is not straightforward. Several channels with opposite effects come into play and the total effect varies among regions and time periods. We believe that one important channel through which subsidies affect agricultural employment in the long run has been overlooked by the literature. This channel is the effect of subsidies on the education level of farmers' children.

When farmers are credit constrained, they may underinvest in their children's education. By increasing farmers' revenues, subsidies allow them to increase investment in education. If children with higher education levels are less willing to work in the agricultural sector then one long term effect of farm subsidies is to reduce labor supply in the agricultural sector.

The aim of this paper is to contribute to analysis of the impact of farm subsidies on agricultural employment by focusing on the education channel. We provide a theoretical model and some empirical evidence supporting our argument.

The rest of the paper is organized as follows. In section 2 we present the theoretical model. In section 3 we present the data, the estimation methods and the empirical results. Section 4 concludes.

---

[3] Note that the data presented in Figure 4 is for Belgium, since no data is available on the EU 15 for this time period. However, for most of the EU 15 countries where we have data on, we find similar results.
[4] An extended version of the paper provides an detail overview of the existing literature.

2. THEORETICAL FRAMEWORK

We build a model of investment in schooling based on Acemoglu and Pischke (2001). The economy is composed of N farmers with revenues w_a, following a cumulative distribution function $F(w_a)$. Each farmer has one child. The game lasts two periods.

In period 1, each farmer consumes c, saves s and invest an amount h to educate his child. He dies at the end of the period.

In period 2, the child's education level is $e = 1$ if parents invested in his education and $e = 0$ otherwise.[5] Each child decides whether to work in the agricultural sector, i.e. overtake his parents' farm, or work in the non-agricultural sector, i.e. take a job in the industrial or services sectors. Child's expected revenue is denoted w_c and his consumption level is denoted $\tilde{c}$. The game ends at the end of period 2.

The farmer is altruistic towards his child. His utility function depends on his consumption level and on his child's consumption level:

$$(c, \tilde{c}) = lnc + \beta ln\tilde{c}, \tag{1}$$

where $\beta < 1$ is the altruism rate.

Each farmer maximizes his utility with respect to his consumption level c, the amount of savings s and his child's education level e, subject to his budget constraint and to his child's budget constraint.

Assuming for simplicity that the interest rate is zero[6], the farmers' and his child's budget constraints are respectively given by:

$$c + he + s \leq w_a \tag{2}$$
$$\tilde{c} \leq s + w_c \tag{3}$$

The child's utility only depends on his consumption level. Therefore the child chooses the employment sector that allows him to earn the highest expected revenue.[7]

We assume that children without education earn the same revenue as their parents, w_a, if they choose to overtake their parents' farm. If they choose to work in the non-agricultural sector, they earn an expected revenue of w_{na}.

Education increases productivity and revenues. We assume that educated children earn $w_a(1 + \theta_a)$ if they choose to work in the agricultural sector and $w_{na}(1 + \theta_{na})$ if they choose to work in the non-agricultural sector, where θ_a and θ_{na} are the rates of return to education in the agricultural and non-agricultural sectors respectively.

We assume that:

$$\theta_{na} > \theta_a > 0, \tag{4}$$

i.e. the returns to education are lower in the agricultural sector.[8]

We assume that education is a pure investment good, i.e. it has no other value than increasing expected revenues.

Agricultural employment in period one is exogenously given by the number of farmers, N. Agricultural employment in period two is endogenously given by the

---

[5] For simplicity we assume the level of education to be a binary variable.

[6] Introducing a positive interest rate would not alter the results.

[7] Other factors than revenue may affect the employment decisions of farmers' children. They may take into account leisure time and the probability of being unemployed in each sector and they may derive additional utility from overtaking their parents' activity. We assume that the monetary values of these other factors are included in the expected revenues of each sector.

[8] Based on a sample of high school graduates in the US, Orazam and Matilla (1991) have shown the returns to schooling are higher for non-agricultural occupations than for agricultural employment.

number of farmers' children who choose to work in the agricultural sector.[9] We denote it $\widetilde{N}$.

Our aim is to assess the impact of farm subsidies on agricultural employment in period two. We solve the model by backward induction. First, we determine child's employment choice for a given education level. Second, we determine parents' education decisions. Finally, we compute agricultural employment in period two and we analyze the effect of subsidies on this variable.

Uneducated children choose to work in the agricultural sector if $w_a > w_{na}$.

Educated children choose to work in the agricultural sector if $w_a(1 + \theta_a) > w_{na}(1 + \theta_{na})$. Assumption (4) implies that all else equal, educated children are less likely to choose the agricultural sector.[10]

We can classify farmers' children into three groups, depending on their parents' revenue. First, children of farmers with revenues w_a such that $w_a < w_{na}$ choose the non-agricultural sector independently of their education level. Second, children of farmers with revenues w_a such that $w_a > w_{na}[(1 + \theta_{na})/(1 + \theta_a)]$ choose the agricultural sector independently of their education level. Finally, children of farmers with revenues w_a such that $w_{na} < w_a < w_{na}[(1 + \theta_{na})/(1 + \theta_a)]$ choose the agricultural sector if and only if they are not educated. Therefore, the educational choices of these intermediate revenue farmers affect agricultural employment in period two.

Since the focus of this paper is the impact of farmers' educational choices on agricultural employment, we restrict our attention to these intermediate revenue farmers, i.e. we assume that the revenue of all farmers is higher than the expected revenue in other sectors for a non-educated person, but lower than the expected revenue in other sectors for an educated person[11]:

$$w_{na} < w_a < w_{na}[(1 + \theta_{na})/(1 + \theta_a)] \tag{5}$$

Assumption (5) implies that a child will overtake his parents' farm if and only if he is not educated. Then, the child's expected revenue can be written as:

$$w_c = w_a + e[w_{na}(1 + \theta_{na}) - w_a]. \tag{6}$$

Each farmer maximizes (1) subject to (2), (3) and (6). We solve parents' optimization problem in two cases. First, we consider the benchmark case in which farmers are not credit constrained, i.e. they can borrow pledging the future income of their child. Second, we consider the more realistic case in which farmers are credit constrained, i.e. they cannot borrow pledging the future income of their child.

2.1. Benchmark case: absence of credit constraints

In this section we suppose that farmers can borrow money in period one, pledging on their child's income in period two. Thus, savings can be negative.

After solving parents' optimization problem, we obtain that parents invest in education if and only if:

$$w_{na}(1 + \theta_{na}) - w_a > h \tag{7}$$

---

[9] We assume that individuals only enter the agricultural sector by taking over the farm of their parents.

[10] Ceteris paribus, the minimum farm revenue inducing a child to choose the agricultural sector is higher when the child is educated: $w_{na}(1 + \theta_{na})/(1 + \theta_a) > w_{na}$.

[11] This assumption reduces the number of cases to be considered and simplifies the reasoning, but it is not driving our results. Similar conclusions can be reached without restricting farming revenues.

The right hand side of (7) is the cost of education. The left hand side of (7) is the benefit of education. As only non-educated children will choose farming, this benefit is equal to the difference between the expected revenue outside agriculture for an educated child and the farming revenue for a non-educated child. In absence of credit constraints, farmers invest in education if and only if the benefit of education exceeds its cost.

Note that the cost of education, h, is the same for everyone, while the benefit of education, $w_{na}(1 + \theta_{na}) - w_a$ is higher for poorer farmers. Therefore, in absence of credit constraints, only the relatively poor farmers, i.e. those with revenues $w_a < w_{na}(1 + \theta_{na}) - h$, invest in education.

The proportion of educated children in period two is then equal to $F(w_{na}(1 + \theta_{na}) - h)$ and agricultural employment in period two is given by:
$$\widetilde{N} = N[1 - F(w_{na}(1 + \theta_{na}) - h)]. \tag{8}$$

Let's now analyze the effect of farming subsidies on $\widetilde{N}$.

Suppose that subsidies increase farming revenues in both periods, from w_a to $(1 + p)w_a$, with $p > 0$. Let $\widetilde{N}(p)$ denote agricultural employment in period two as a function of subsidies.

Children of farmers with revenues w_a such that $w_a > w_{na}[(1 + \theta_{na})/(1 + \theta_a)]/(1 + p)$ will choose the agricultural sector independently of their education level. The proportion of farmers in this interval whose child will take over the farm is thus equal to 1, while it was $1 - F(w_{na}(1 + \theta_{na}) - h) \leq 1$ in absence of subsidies.

Children of farmers with revenues w_a such that $w_a < w_{na}[(1 + \theta_{na})/(1 + \theta_a)]/(1 + p)$ will choose the agricultural sector if and only if they are not educated. These farmers invest in education if $h < w_{na}(1 + \theta_{na}) - w_a(1 + p)$.[12] The proportion of farmers in this revenue range whose child will take over the farm is thus equal to $1 - F([w_{na}(1 + \theta_{na}) - h]/(1 + p))$.[13] In absence of subsidies, this proportion was lower. Indeed, as F is a cumulative distribution function, $1 - F(w_{na}(1 + \theta_{na}) - h) \leq 1 - F([w_{na}(1 + \theta_{na}) - h]/[1 + p])$.

Thus, we can state:

Result 1 *In absence of credit constraints, subsidies have a positive impact on agricultural employment in the next generation.*

Note that if subsidies are sufficiently high, all farmers' revenues satisfy $w_a < w_{na}[(1 + \theta_{na})/(1 + \theta_a)]/(1 + p)$ and all children will choose to become farmers. Given assumption (5), a sufficient condition for this to happen is:
$$1 + p \geq (1 + \theta_{na})/(1 + \theta_a). \tag{9}$$

3.1. Realistic case: presence of credit constraints

In this section we suppose that farmers cannot borrow money in period one, pledging on their child's income in period two. Thus, savings cannot be negative.

Then parents maximize (1) under (2), (3), (6) and the positive savings constraint:
$$s \geq 0 \tag{10}$$

Solving this optimization problem, we obtain that parents invest in education if:
$$f(w_a) \equiv [(w_{na}(1 + \theta_{na}))^\beta (w_a - h)]/w_a^{\beta+1} > 1 \tag{11}$$

---

[12] The solution to the maximization problem of these farmers is obtained by replacing w_a with $w_a(1 + p)$ in the initial problem.

[13] This is the proportion of farmers who do not invest in education.

The probability that a farmer invests in his child's education, i.e. the probability that (11) is satisfied, decreases with the cost of education, h, and increases with the non-agricultural skilled wage, $w_{na}(1 + \theta_{na})$. The impact of farmer's revenue on this probability is not straightforward. One can check that $f(w_a)$ is increasing in w_a for $w_a < w_a^*$ and decreasing in w_a for $w_a > w_a^*$, where $w_a^* = (\beta + 1)h/\beta$. This means that increasing poor farmers' revenues has a positive impact on investment in education, while the opposite is true for rich farmers.

The relationship between farming revenue and investment in education is non-monotonic because revenue has two opposite effects on farmers' educational choices. On the one hand, as farming revenue increases, the benefit of education decreases, so investment in education should decrease. On the other hand, as revenue increases, credit constraints become less binding, so investment in education should increase. The positive effect of revenue is dominant as long as $w_a < w_a^*$.

Let $\underline{w_a}$ and $\overline{w_a}$ be the solutions to $f(w_a) = 1$, with $\overline{w_a} > \underline{w_a}$. Farmers with revenues w_a such that $w_a < \underline{w_a}$ do not invest in education because they are credit constrained, and farmers with revenues w_a such that $w_a > \overline{w_a}$ do not invest in education because the returns are not sufficiently high. Farmers with revenues $\underline{w_a} < w_a < \overline{w_a}$ invest in education. Then agricultural employment in period two is equal to:

$$\widetilde{N} = N(F(\underline{w_a}) + 1 - F(\overline{w_a})). \tag{12}$$

Let's now analyze the effect of subsidies on $\widetilde{N}$. As in the previous section, suppose that subsidies increase all farming revenues from w_a to $(1 + p)w_a$.

Children of farmers with revenues w_a such that $w_a > w_{na}[(1 + \theta_{na})/(1 + \theta_a)]/(1 + p)$ will choose the agricultural sector independently of their education level. The proportion of farmers in this revenue range whose children will work in agriculture is 1. Thus subsidies increase the proportion of successors for farmers in this revenue range.

Children of farmers with revenues w_a such $w_a < w_{na}[(1 + \theta_{na})/(1 + \theta_a)]/(1 + p)$ will choose the agricultural sector if and only if they are not educated. These farmers invest in education if $f_p(w_a) \equiv f(w_a(1 + p)) > 1$. The proportion of farmers in this revenue range whose children work in agriculture is $F\left(\underline{w_a}/(1 + p)\right) + 1 - F\left((\overline{w_a}/(1 + p))\right)$, while it was $F(\underline{w_a}) + 1 - F(\overline{w_a}) \leq 1$ in absence of subsidies. Subsidies increase the proportion of successors for farmers in this revenue range if and only if:

$$F(\overline{w_a}) - F((\overline{w_a})/(1 + p)) < F\left(\underline{w_a}\right) - F\left(\underline{w_a}/(1 + p)\right) \tag{13}$$

The right hand side of (13) is the proportion of farmers who are able to invest in education thanks to subsidies. The left hand side of (13) is the proportion of farmers who are not willing to invest in education because of subsidies.

These different farmers are represented in Figure 4. If the proportion of farmers with revenues between $(\overline{w_a})/(1 + p)$ and $\overline{w_a}$ is sufficiently high, i.e. if $F(\overline{w_a}) - F((\overline{w_a})/(1 + p)) > F\left(\underline{w_a}\right) - F\left(\underline{w_a}/(1 + p)\right)$, then subsidies have a negative impact on agricultural employment in period two.

As in the previous section, if p is sufficiently high, all children will become farmers, i.e. sufficiently high subsidies increase agricultural employment.

Figure 4: Farmers' revenues and succession
Hence, we can state:

Result 2 *In presence of credit constraints, subsidies may have a positive, a nil or a negative effect on agricultural employment in the next generation. A negative effect is more likely when subsidies are not too high and when the proportion of poor farmers is important.*

Our theoretical framework shows that credit constrained farmers under invest in their children's education. An increase in their revenues through subsidies would increase the education levels of their children, accelerating migration out of agriculture in the next generation. The following section provides some empirical evidence supporting this argument.

3. **EMPIRICAL FRAMEWORK**

3.1.Data

We use data from the European Community Household Panel (ECHP). This is a survey based on a standardised questionnaire that involves annual interviewing of a representative panel of households and individuals in each country. The sampling scheme of the panel allows identifying identical individuals and households in different years. This allows us to identify children and their parents in two different waves.

From the first wave, collected in 1994, we selected households in which at least one of the parents was self-employed in the agricultural sector. We only consider self-employed farmers because most of the farms in the EU-15 are family farms and succession takes place within the household (Stiglbauer and Weiss, 2000). We included information on household characteristics, parents' income and education level. From the sixth wave, collected in 1999, we selected the children of households which were in the education system in 1994 and finished their studies.[14] We gathered information on their current employment sector, their highest level of education and some personal characteristics.

Our dataset contains 97 individuals from Portugal, Spain, Italy and Ireland. For the other EU-15 countries, we were not able to identify a sufficient number of individuals self-employed in agriculture.

---

[14] The choice of using data from the first and the sixth wave was purely arbitrary.

Unfortunately, the dataset does not include any information on the level of agricultural subsidies received by each farmer. Our approach is to assume that subsidies increase farming revenue by a given factor and to estimate the marginal impact of farming revenue on the education level and employment sector of farmers' children.

3.2. *Empirical Specification and Variables*

In order to assess the marginal impact of farming revenue on the education level and employment sector of farmers' children, we estimate an econometrical model in which we assume the educational and occupational decisions to be jointly determined.[15] We estimate the following model:

$LEAVE_i = \alpha_0 + \alpha_1 SCHOOL_i + \alpha_2 SELF_i + \alpha_3 WAGE_i + \alpha_4 GENDER_i + \alpha_5 HHSIZE_i + \alpha_6 AGSIBLING_i + \alpha_7 SCHOOLPAR_i + country\ dummies + \varepsilon_i$

$SCHOOL_i = \beta_0 + \beta_1 LEAVE_i + \beta_2 SELF_i + \beta_3 WAGE_i + \beta_4 GENDER_i + \beta_5 HHSIZE_i + \beta_6 AGSIBLING_i + \beta_7 SCHOOLPAR_i + \beta_8 ALLOWANCE_i + country\ dummies + \mu_i$ (15)

LEAVE is a dummy variable which takes the value of 1 if the child is not employed in the agricultural sector in 1999, and zero otherwise. Since the returns to schooling are expected to be higher outside the agricultural sector, individuals who already decided to leave the agricultural sector are expected to take up more education compared to those that decided to stay in agriculture and hence it is expected that LEAVE has a positive impact on the level of schooling of the child.

SCHOOL is the natural logarithm of the number of years of full time education of the child in 1999. We expected SCHOOL to have a positive impact on the probability to leave agriculture as the returns to schooling in non-agricultural employment are higher compared to agricultural employment.

SELF is the natural logarithm of self-employed farming income of the parents in 1994 (PPP adjusted, in euros).[16] We expect this variable to have a negative impact on the decision to leave agriculture, once education is controlled for, since it is a proxy for child's expected income in the agricultural sector. However, we expect a positive impact of SELF on the level of schooling of the child as a higher income reduces credit constraints of the parents which allows them to invest (more) in the education of their children.

WAGE is dummy variable which takes the value of one if the main source of income for the parents comes from an employment different from farming in 1994, and zero otherwise. Parents with an off farm employment experience acquire additional skills/information/networks to those useful in farming. If these assets are transmitted to children, the latter will be more likely to find an off farm employment themselves (Hennessey and Rehman, 2007). Being employed in another sector may also encourage parents to invest in the schooling of their children as they have a positive attitude towards working in off farm employment and they want to encourage their children to also take up employment in the non-agricultural sector. Therefore we expect that WAGE has a positive impact on the level of education of the child.

In addition, we include control variables related to the household or personal characteristics of the child. GENDER is a dummy variable that takes the value one if the

---

[15] This approach is similar to Hennessey and Rehman (2007).

16 We also include the squared term of self-employed income in the regression, but we did not find evidence of a non-linear impact, which could be related to the nature of the sample.

child is a woman, and zero if the child is a man.[17] We expect a positive impact of GENDER on the decision to leave agriculture and a positive effect of GENDER on the level of education of the child. HHSIZE is the household size of the family in the first wave, measured by the number of adult equivalents according to the OECD equalized scale. We expect HHSIZE to have positive impact on the decision to leave agriculture, while the effect of HHSIZE on the level of schooling of the child is not straightforward. AGSIBLING is a dummy variable that takes a value of one if the child has a sibling which is also employed in the agricultural sector, and zero otherwise. The effect of AGSIBLING on the decision to leave the agricultural sector can be ambiguous. SCHOOLPAR is a dummy variable that takes the value of one if one of the parents has completed secondary education. We expect SCHOOLPAR to have a negative impact on the probability that children leave agriculture.[18] In addition, we expect SCHOOLPAR to have a positive impact on the level of schooling of the child.

In order to eliminate the simultaneity bias due to the fact that educational and occupational decisions are jointly determined , we will estimate the model using an IV procedure. We instrument the variable SCHOOL with the level of education allowances received by the parents. Education allowances are expected to have a positive impact on the level of schooling of children[19], and there is no obvious reason why they should affect children's employment decisions other than through education. The instrumental variable ALLOWANCE is the natural logarithm of the education allowance received by the parents (PPP-adjusted, in euros), to which we added one euro to ensure that it takes the value zero for households that do not receive education allowance.

Country dummies control for country fixed effects.

3.3   Results

Table 1 gives the estimation results for the estimation model.[20]

In the first stage regression, ALLOWANCE is positively correlated with children's schooling at the 1% level, which is an indication that the instrument is valid. SELF has a positive and significant effect on children's schooling, which indicates that an increase in farming will lead to a higher level of schooling of the child. This suggests that subsidies may play an important role in overcoming farmers credit constraints such that they are able to invest (more) in their children's education. AGSIBLING has a positive and significant impact on children's schooling. This suggests that when already one of the children is working in agriculture the parents may decide to invest in the schooling of the other children because there may be not sufficient work for both children on the farm.

In the second stage regression, we find that children's schooling has a positive and significant effect on the probability to leave the agricultural sector. Evaluated at the mean level of schooling, a 10% increase in schooling increases the probability of leaving agriculture by 22%.

---

[17] Some studies found that the probability of succession is negatively correlated to the number of daughters (e.g. Glauben et al., 2004;, 2009)

[18] More educated farmers are more likely to adopt new technologies and more modern and efficient farms may be more attractive for farmers' heir (e.g. Mishra et al., 2004; Stiglbauer and Weiss, 2000).

[19] An indicator for a good instrument is that the correlation between the instrument and the variable for which one instruments is high. This holds in our case and the correlation between SCHOOL and ALLOWANCE is high, namely 19%.

[20] In addition, we also performed several robustness checks, but due to size limitations these are not only included in a more extended version of the paper. First, we estimates equation (16) using two stage least squares instead of instrumental probit. Second, we estimate equation (16) using a different measure for children's education level. Instead of the number of years of schooling, we use the dummy variable HIGH, which takes the value one if the child completed secondary education.

Once education is controlled for, parents' farming income has a negative impact on children's decision to leave agriculture, as expected from the theoretical model. Evaluated at the mean self-employed farming income, a 10% increase in farming income decreases children's probability of leaving agriculture by 1.5%.

AGSIBLING has a negative and significant impact on the probability to leave agriculture, indicating that when of his siblings is working in agriculture the child will be less likely to leave the agricultural sector.

These findings support the theoretical analysis of section 2. Increases in farming revenues are partly used for investing in the education of farmers' children and they decrease the probability that those children will become farmers.

4. **CONCLUSION**

Agricultural employment in western countries has been steadily decreasing in the past decades, despite important levels of farm subsidies. Studies that have analysed the impact of subsidies on agricultural employment arrived to contradictory conclusions, suggesting that their direct positive effect on agricultural labour supply is sometimes counterbalanced by indirect negative effects. In this paper we argue that that one such indirect effect, overlooked by the literature so far, is the impact of subsidies on farmers' children' education.

The evolution of agricultural employment largely depends on the willingness of farmers' children to overtake their parents' activity. By increasing farmers' revenues, subsidies allow them to increase investment in their children's education. Children with higher education levels have access to better paid jobs in the industrial or services sectors. They are therefore less likely to be willing to work in the agricultural sector. We presented a theoretical model and empirical evidence supporting this argument.
