THE IMPACT ON METROPOLITAN AREAS OF HINTERLAND RESOURCE DEPLETION

M. Jarvin Emerson and Hossein Akhavi-pour*

"The life span of intensive development of natural resources is usually short, as increasing inaccessibility of resources lowers the return to capital. Continuous growth is rare, since it requires the creation of urban agglomeration economies — an unlikely occurrence in view of the low labor requirements of natural-resource development. Natural resource zones usually function as enclaves and fail to generate broad economic expansion." [8]

This view of the role of resource development is contrasted with that of Perloff *et al* [6] among others who associate much of historical regional development with resource development.

The focus of this paper is on the association between resource development and metropolitan economies in the mid-continent region of the U.S. The concern is with modeling the potential impacts of a declining resource on adjacent metropolitan areas. The objectives are twofold: (1) to attempt to model the major impacts and (2) to determine if the impacts are significant.

The Resource Problem

Underlying a major portion of what is referred to as the High Plains or Great Plains of the U.S. is the Ogallala aquifer which has provided water for agricultural irrigation for the past 30 years. An approximation of the location of the aquifer appears in Figure 1. About 150 counties and 180,000 square miles overlie the aquifer.

Prior to 1950 the High Plains was a dryland cattle grazing and wheat production area, a reflection of 15-18 inch average rainfall in the area. In the early to mid-1950s the availability of low-cost natural gas as a pumping fuel facilitated a rapid growth of irrigation development. Irrigation brought huge increases in feed grain production which in turn helped create a new activity for the region — cattle feedlots. The six states which contain the major part of the Ogallala aquifer accounted for about 40 percent of the nation's cash receipts from cattle.

* Kansas State University and University of Minnesota, respectively. This paper has benefited from comments of participants in the Advanced Summer Institute in Regional Science, Umea, Sweden, June 1986. Financial support from the Kansas Agricultural Experimentation and the Economic Development Administration, U.S. Department of Commerce is gratefully acknowledged.

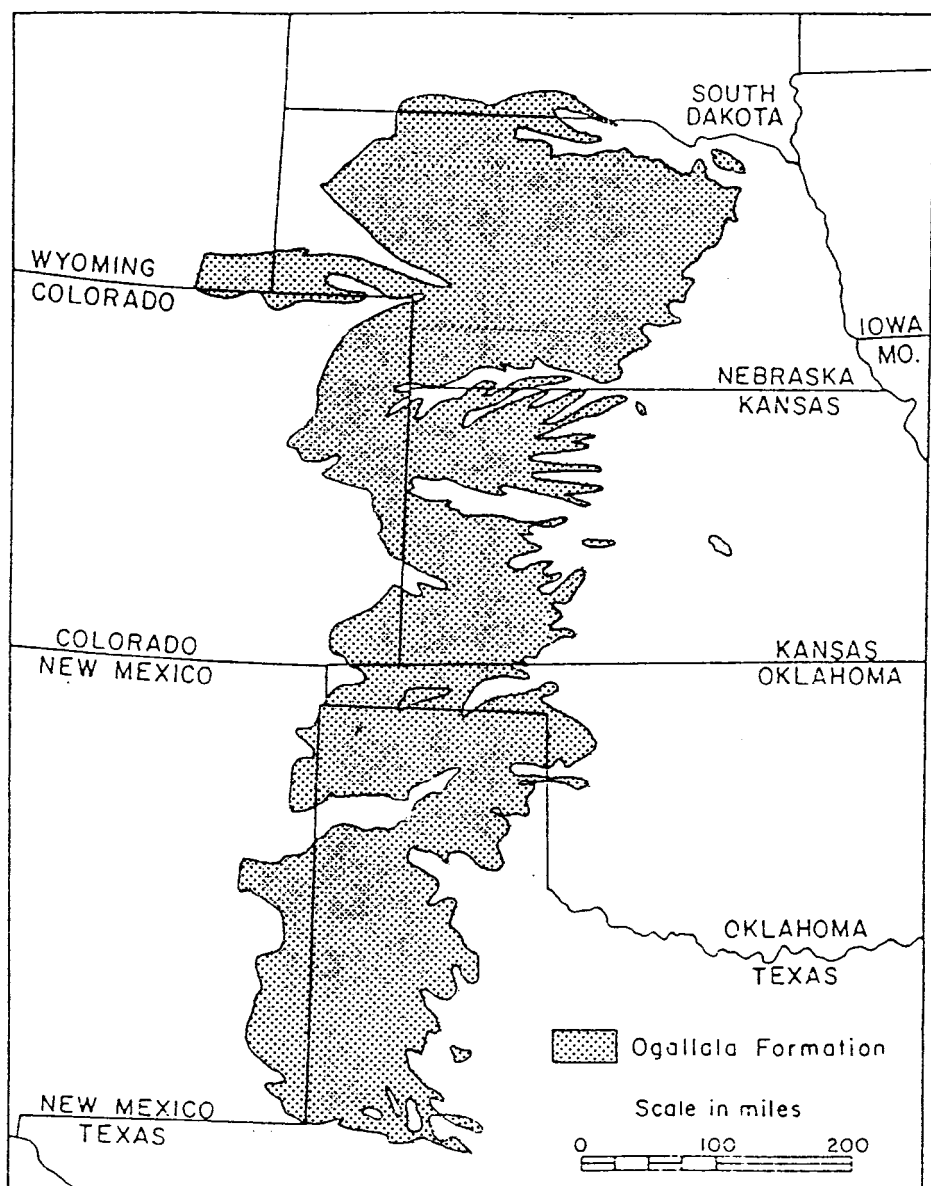

FIGURE 1. GENERALIZED DISTRIBUTION OF THE OGALLALA FORMATION

The feedlot industry has attracted meat packing plants to the region and new plants continue to be built. The world's two largest meat packing plants have been built in the High Plains region of Kansas in recent years. Associated with these developments are, of course, a variety of other linkages to be discussed below.

The Ogallala aquifer, which underlies this substantial development, is being depleted. Irrigated acreage, a trivial amount in 1950, totaled 15 million acres in 1980. Since the aquifer has a very slow rate of recharge, most of the water being pumped for irrigation is essentially being mined since it is a non-renewable resource.

Compounding the declining groundwater levels is the increasing cost and reduced availability of natural gas to operate the pumps. The declining water levels in the aquifer have already resulted in the cessation of irrigation in some areas of the High Plains region.

The Research Problem

A \$6 million Economic Development Administration grant financed research on the economic impact of declining groundwater irrigation in the High Plains region of the U.S. That study, completed four years ago, focused largely on the impacted areas, the six-state area and the national economy [4, 5]. A level of impact ignored by that study is that of the metropolitan areas within or adjacent to the Ogallala region. The purpose of this paper is to explore some approaches to modeling the economic impact of reduced irrigation and associated declines in agricultural production on the adjacent metropolitan areas.

Regional economic decline is not a popular spectator sport either for participants or for economic researchers. Abundant literature exists on regional and urban economic growth and development. Little attention has been focused on the economics of decline. Even the substantial attention paid to "lagging" or "distressed" regions is growth oriented. Notable exceptions to the lack of studies of economic decline include impact analyses of military base closures.

Although traditional regional economic impact models have varied in sophistication from simple economic base models to dynamic input-output models or econometric models, they have shared a common orientation. The driving mechanism of these models has been some type of change in external demand for the region's products. The models translate the demand changes into total and component impacts on the urban-regional economy. However, if the initial change is of supplying origin, impacts models are rare.

Selecting an Impact Model

Three different models were considered as potential impact frameworks: economic base models, econometric models, and input-output models. The first two were rejected for reasons explained below.

The econometric model seemed to offer little prospect because of a lack of

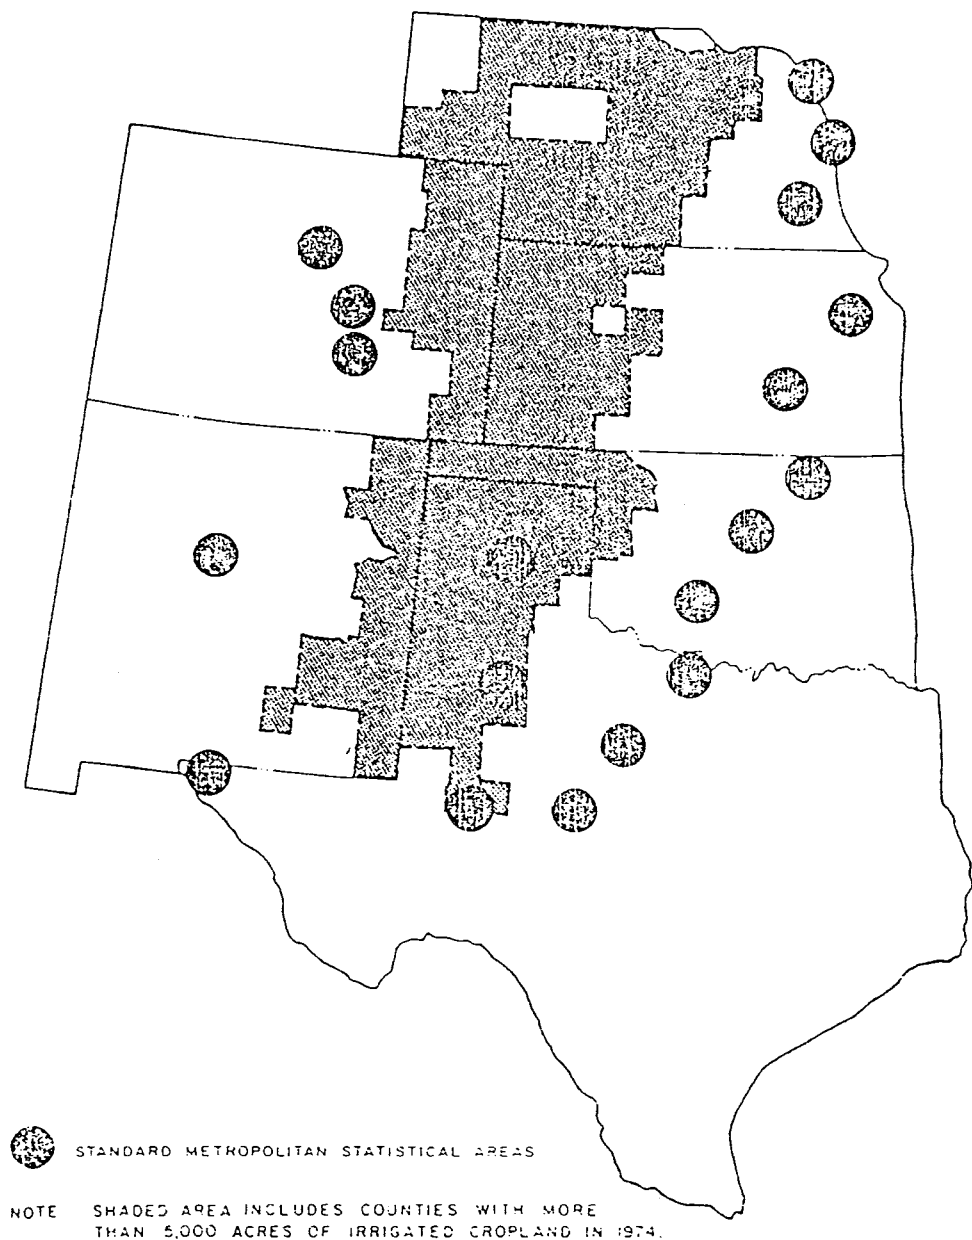

FIGURE 2. CROP PRODUCTION AND POPULATION CENTERS IN THE OGALLALA REGION

time series data to estimate structural relations. Furthermore, in econometric analysis turning points or the switching of phases have not been successfully modeled. In fact times series models more often than not exclude certain periods in estimating model parameters with the rationale that the inclusion of these unusual periods will bias the "normal" structure.

Economic Base Models

The rudiments of the economic base model can be illustrated as follows:

$$Y_i = (E_i - M_i) + X_i$$

Y_i = total income in region i

E_i = local spending (including C, I & G)

M_i = imports into region i

X_i = exports in region i

$$E_i = e_i Y_i$$

$$M_i = m_i Y_i \text{ and } X_i = \bar{X}_i$$

$$Y_i = e_i Y_i - m_i Y_i + \bar{X}_i$$

$$\therefore Y_i = \frac{\bar{X}_i}{1 - e_i + m_i}$$

$$K = \frac{dY_i}{dX_i} = \frac{1}{1 - e_i + m_i} = \frac{Y_i}{\bar{X}_i}$$

An economic base model is a rather limp effort to model the multi-dimensional impacts outlined above. If we were to attempt to implement the model using the location quotient approach (which may have as many weaknesses as the economic base model itself), the results are as indicated in Tables 1 and 2.

The location quotients were calculated as:

$$\frac{R_A/R}{N_A/N}$$

$$N_A/N$$

where

R_A = regional employment in industry A

R = total regional employment

N_A = national employment in industry A

N = total national employment

Transportation, trade, F.I.R.E. * and services are economic base components. Among the manufacturing sectors only electrical machinery and printing and publishing are significant exporters. The Wichita SMSA is heavily influenced by aircraft manufacturing. Food processing is the other part of the manufacturing economic base. Trade, finance, and services reflect the regional trade center function of the SMSA.

Such an approach has been widely criticized in the literature and will certainly not be defended here. It is presented by way of contrast with the input-output alternative.

The basic problem with the economic base approach is that it focuses on exports when a significant part of the problem at hand is with reduced imports with a few substitution possibilities.

The economic base approach views imports as a function of regional income or product not as a potential production constraint. Also for the problem at hand such an approach does not facilitate the analysis of structural change.

An Input-Output Approach

In order to model the types of impacts identified above, it is necessary to consider two different effects [see 9]. First, traditional impact analysis focuses on demand changes as "induced by" effects. These are the consequences of changes in the markets for agricultural inputs and associated indirect requirements. Second, reduced agricultural production will reduce imports of grain and livestock products for processing, the "stemming from" effects.

The input-output model has the potential to measure the supply impacts as well as the traditional demand impacts. The impact of a change in demand is a relatively straight-forward traditional use of input-output as described above.

The analysis of supply short-falls in particular sectors is less traditional. Supply restrictions have been analyzed with linear programming when the restricted input was ubiquitously required by the region's industries. The L-P approach was to attempt to maximize regional output or income with a fixed quantity of some input such as energy or water. The problem confronted here is a different type of supply restriction in that it represents reduced input into only one industry (or at most a few) where other industries do not compete for this input.

One possible approach to this problem is to partition the matrix and vectors as follows:

$$\begin{bmatrix} X_r \\ X_u \end{bmatrix} = \begin{bmatrix} A_{rr}/A_{ru} \\ A_{ur}/A_{uu} \end{bmatrix} \begin{bmatrix} X_r \\ X_u \end{bmatrix} + \begin{bmatrix} Y_r \\ Y_u \end{bmatrix}$$

where X_r = output vector of restricted products
 X_u = output vector of unrestricted products
 Y_r = final demand vector of restricted products
 Y_u = final demand vector of unrestricted products
 A_s = respective partitions of coefficient matrix
 $X_u = (1 - A_{uu})^{-1} (A_{ur}X_r + Y_u)$

indicates the output levels for unrestricted products

$$Y_r = [1 - A_{rr} - A_{ru}(1 - A_{uu})^{-1}] X_r - A_{ru} (1 - A_{uu})^{-1} Y_u$$

indicates that the final demands for restricted products are connected by a general linear transformation with the final demands for unrestricted products.

Alternatively, if relatively few sectors are affected by reduced imports, outputs may be restricted by the new lower impact levels where

$$a_{mj}x_j \leq M_j$$

where a_{mj} is the input coefficient for sector j and M_j is the maximum imports available.

Impact Sensitivities

Two metropolitan areas were selected for analysis because of the availability of input-output models. A survey data input-output model was available for Wichita and a secondary data table for Kansas City. Both provided enough detail for the demonstration modeling.

The basic question is whether adjacent SMSA's are likely to be significantly affected by the potential return to dryland agriculture in a significant portion of the Great Plains. At minimum the analysis attempts to identify the potential magnitude of this impact through some sensitivity analysis to determine if a more rigorous analysis would be appropriate. The approach then is to "shock" the economic structure of an SMSA that is adjacent to the H-P region to determine its sensitivity to H-P the current agricultural complex. The simulations are intended to ascertain the general sensitivity, not the precise magnitudes. This approach may then lead to a more rigorous modeling approach once we know something about the sensitivity of the economy to the impact.

Two different scenarios are considered. The first is that crop production declines and sets off a decline in feedlots and local processing. The second scenario is that crop production declines but feedlot cattle operations continue because environmental factors favor a High Plains location. At this point in the research, calibration of demand and supply shifts is tentative.

TABLE 3
Input-Output Simulations

Simulation 1: Contraction in both Grain and Livestock Production
(thousands of dollars)

	Induced by Effects	Stemming from Effects
Wichita	637,504	320,072
Kansas City	964,173	297,284

Simulation 2: Contraction in Grain Production
(thousands of dollars)

	Induced by Effects	Stemming from Effects
Wichita	221,145	104,001
Kansas City	592,179	223,951

The results of the scenarios appearing in Table 3 show the magnitude of the potential impacts to be substantial. The impacts are relatively different for the two SMSAs. Wichita is relatively more influenced by supply restrictions than Kansas City. Because of its smaller size the relative impact on Wichita is greater.

For the Kansas City economy the results indicate that the greatest impact will be on industries serving H-P agriculture most notably marketing, finance, and transportation. For the Wichita economy the most significant impact is on the supply side where industries directly or indirectly using H-P agricultural products will be relatively most affected.

Kansas City, on the other hand, is a major funnel through which H-P agriculture passes because it is a transportation hub with associated communication and financial services.

Structural Change

A third scenario was considered where food processing industries were eliminated when the supply of crops and livestock dropped below a threshold level. The elimination of several industries will change the structure of SMSA economy. An approach to anticipating the significance of this change is via the recalculation of multipliers to determine how the leverage effects have changed. A comparison of output multipliers appears in Tables 4 and 5 indicating reductions in multiplier values particularly for those industries tied to the food processing sectors.
