SUMMARY

Publicly available data on grain elevators are inadequate for the Government decisionmaking process relating to the regulation of dust emissions. Such data consist basically of lists which give addresses, storage capacity, and receiving and shipping capacities. The data fail to indicate which facilities should be subject to regulations, since neither function of the structure nor average annual throughput, the volume of grain handled, is listed. Annual throughput data would best allow officials to determine the volume of grain with dust emission potential. As is often the case with data necessary for making compliance regulations, this information is private.

The study analyzes data furnished by an industry survey of six grain belt States. Regression analysis of the data revealed that no strong relationship exists between annual throughput and the various characteristics of elevators, including storage capacity, the most publicly documented characteristic of grain elevators.

Because of the differences among grain elevators, it is virtually impossible to use publicly available statistics to write blanket regulations having an equal impact on all such structures. Thus, a survey statistically designed to obtain the proper kind of data is needed to evaluate properly the potential impacts of proposed regulations affecting operational characteristics of grain elevators.

NUMBER AND PHYSICAL CHARACTERISTICS OF GRAIN ELEVATORS

by L. D. Schnake and James L. Driscoll $\frac{1}{2}$

INTRODUCTION

Government officials considering programs and regulations affecting agribusiness industries need a thorough understanding of the industry with which they are dealing. In this report, various statistics and analyses useful to grain marketing researchers, industry, and those needing documentation on grain elevators are organized into four major parts: 1) Historical development of the grain marketing system, its organization, and practices; 2) estimates of the U.S. grain elevator universe; 3) physical aspects of grain elevators; and 4) regression analyses to predict grain throughput. Because of a lack of geographically diverse data, available data are more representative of the number of grain elevators than of regional differences among them. These data provide limited statistics for impact analyses, and point out the numerous variables which must be considered to properly conduct such analysis.

THE GRAIN MARKETING INDUSTRY

The grain marketing industry consists of an interrelated network of producers, physical facilities, merchants, and processors whereby seasonally produced commodities are transformed into consumer products or exported on a continuous basis. Between producers and consumers are various points of grain storage, including farm storage; country, subterminal, and terminal elevators; mills and other processors; and other elevators. Grain elevators are commonly classified as country, subterminal, and terminal, although there are no precise definitions for such classifications (4). 2/

<u>1</u>/ Agricultural Economist, Grains and Feeds Program Area, Commodity Economics Division, Economics, Statistics, and Cooperatives Service, stationed at the U.S. Grain Marketing Research Center, Manhattan, KS; and former Agricultural Economist, Commodity Economics Division, Economics, Statistics, and Cooperatives Service, stationed in Washington, D.C.

^{2/} Underscored numbers in parentheses refer to literature listed in the references section at the end of this report.

Development

In the development of the industry, the country elevator represented the point at which grain was sold by farmers. Country elevators developed as a series of way stations every few miles along rail lines. Concentration of production, quantity of sales from farms, and the distance grain could be hauled by horse and wagon were major factors influencing elevator size and the distance between elevators.

Terminal elevators were located in market centers where facilities existed for bringing buyers and sellers together to inspect grain, determine price, and transfer ownership. Country elevators consigned grain to a representative at these centers and were the owners until a bargain was struck. Much of the grain moving through the marketing system was shipped through these centers.

Development of better communications, standardized grain grading, commercial feeding, increased size of processors, growth of the export market, an evolving rail rate structure, improved highways and waterways, and other forces have caused significant changes. Recently, less grain moves exclusively in the country-terminal-user chain since there are more direct shipments from country points to final destination, especially in the case of exports.

Today, improved roads and transportation equipment make the distance from farm to elevator a much less important determinant of structure of the country elevator system. However, both production and sales from farms have increased substantially, providing a larger volume of business for country elevators. Thus, marketing patterns are influential in the location of storage, and these patterns vary geographically.

In some areas, farmers typically deliver a high percentage of their grain to elevators during harvest. In these areas, country elevators with large storage and handling capacities relative to annual throughput are needed. In other areas, farmers store much of their grain on the farm and deliver a smaller proportion of the crop during harvest, thus reducing the ratio of storage capacity to throughput, and permitting relatively smaller handling capacities. Some of the factors which influence these marketing patterns are ease of quality control in onfarm storage (related in part to climatic conditions), speed of harvest and use of custom services, potential for premiums (such as those based on the level of protein in wheat), tradition, and optimization of the farmers' seasonal workload.

In areas where much of the grain is delivered to country elevators at harvest, immediate shipment to other elevators in the marketing system is often needed to make room for additional farmer deliveries. This need led to the development of storage centers to serve as "surge tanks" in locations outside the traditional terminal markets. These elevators came to be called subterminal elevators. They provide functions such as blending to achieve greater uniformity of grain and facilitate marketing. Storage at an intermediate point in marketing channels also offers the ability to move grain quickly to the final position when needed. Thus, subterminal elevators have a year-round demand for their services.

As the grain marketing system becomes more complex, 3/ other factors besides farmer marketing patterns, such as changes in the freight rate structure, have become influential in the location of new storage facilities. For example, freight rates in some areas have encouraged construction of elevators with high speed loading capacities that require unit-train shipments for efficient facility utilization. There is, of course, a limit to the need for such facilities, since unit-train movements of grain are suitable for export shipments but impractical for most domestic situations.

3/ For more detailed information on the grain marketing system, see (3) and (4).

The Future

The grain marketing system will continue to evolve as economic forces cause changes in its structure. Because of the inherent nature of the task to be performed and the products handled, basic components of the system will probably remain the same. Farmers will continue to do the majority of their business with elevators located near production, and subterminals and terminals will continue to serve as "surge tanks" to even the flows from point of production to point of use, and to facilitate blending. The distinction between subterminal and terminal elevators will become increasingly blurred so that in time there may be no distinction. Many elevators will serve as specialized structures--to load multicar rail units, barges, and ships--while the more traditional elevators will continue to serve the needs of domestic processors and feeders.

The quantity of grain marketed is expected to increase to meet added demands generated by an increasing world population and improved economic well-being. This change, however, is largely independent of the structure of the grain assembly complex. The number of firms will likely continue to decrease while their average size increases, as in the past. However, increased business and specialization are stabilizing forces which will support the number of firms in the future. Increasing concentration of ownership and control may result in emergence of two simultaneous patterns of physical plant structure: 1) Existing storage facilities and equipment will remain in service, merely changing ownership; and 2) new, larger elevators will be built as the primary storage and handling facility, while older, generally smaller elevators are relegated to collection points, abandoned, torn down, or converted to handling other bulk materials. Two or more elevators under single ownership in the same vicinity may give some firms greater transportation versatility. Purchase of an elevator located on a different railroad, for example, might enable a firm to compete more effectively in certain markets.

USDA LISTS PERTAINING TO GRAIN STORAGE CAPACITY

Data concerning numbers and capacities of grain elevators are incomplete; thus it is difficult to establish the size of this universe or the number of a particular type of elevator, such as country, subterminal, terminal, or feed mill. Within USDA, the Agricultural Stabilization and Conservation Service (ASCS), and the Economics, Statistics, and Cooperatives Service (ESCS) 4/ maintain lists pertaining to grain storage facilities which are considered official. The lists are different, however, and are maintained to satisfy the needs of the respective agencies.

ESCS List of Grain Storage Structures

The Statistics Program of ESCS, formerly the Statistical Reporting Service (SRS), maintains a list of off-farm storage facilities for estimating off-farm grain stocks in its quarterly report of grain stored on- and off-farms in the United States.

The ESCS list includes structures used for the storage of grains, soybeans, and flaxseed, and excludes structures used to store only rice or peanuts, oilseed crushers processing only cottonseed or peanuts, tobacco and seed warehouses, and storage that handles only dry beans or peas. This list includes storage structures servicing commercial cattle feedlots, poultry production operations, feed mills, and similar business enterprises. In a few instances, this list includes only the headquarters for a

3

^{4/} On January 1, 1978, three USDA agencies--the Economic Research Service, the Statistical Reporting Service, and the Farmer Cooperative Service--merged into a new organization, the Economics, Statistics, and Cooperatives Service.

particular firm and not its several storage facilities. Thus, the list is not allinclusive for structures capable of serving as grain storage and handling operations. In April 1977, SRS (now ESCS) listed 14,680 off-farm storage facilities (6).

In 1975, the Economic Research Service (now ESCS) used the SRS list for a probability survey of the industry (2). Respondents were asked to classify their firm in one of ten categories: country, subterminal, terminal, or export elevator; soybean processor; flour mill; feed mill; cattle feedlot; poultry producer; or other. Using addresses on the SRS list, ERS estimated that about 8,600 were country elevators and 450 were subterminal and terminal elevators. These estimates were derived by expansion to the universe represented by the ESCS list. This number declined slightly in the April 1977 estimates; thus, estimates of country and terminal elevators and the number of structures should still be valid.

ASCS List of Warehouses Approved Under the Uniform Grain Storage Agreement

ASCS manages inventories of grain acquired by the U.S. Government through price support programs of the Commodity Credit Corporation (CCC). That organization contracts with operators of commercial grain storage facilities for handling and storing these inventories. Since farmer-owned grain pledged under price support loans with the CCC and stored off-farm must be stored in an approved warehouse, there is a strong incentive for elevator owners in major producing areas to enter into a contractual arrangement known as a Uniform Grain Storage Agreement (UGSA) with CCC whenever inventories of grain under loan are desired or expected. Rice under loan is covered by the Uniform Rice Storage Agreement (URSA).

ASCS classifies grain warehouses under the UGSA as terminal or country elevators according to their ability to furnish official weights and grades on receipts and shipments (5). Official weights and grades normally are available only at elevators classified as subterminal and terminal; however, an elevator able to furnish official weights and grades can be classified in the other category. Thus, while it is acceptable to categorize these approved warehouses as terminal and country elevators, one must recognize that the distinction is not absolute.

ASCS also allows a warehouseman to include several distinct storage structures under the same contract if certain conditions are satisfied. For example, an elevator company with a main elevator at location X and satellites at nearby locations Y and Z may place all three storage structures under the same contract if rail transportation rates and tariff rates are identical. These data would be entered into the system under a single warehouse code number with approved storage capacity equal to the sum of the storage capacity at the three locations.

The number of contracts approved under the UGSA may fluctuate from time to time. If inventories of grain are desired or expected, the competitive position of an elevator may depend on gaining control of farm-originated grain; the lack of a contract under the UGSA restricts this competitive position under such conditions. Thus, one could expect a higher number of contracts under the UGSA during such periods, compared with periods of high throughput such as the record export years 1972-76. Elevator owners have less incentive to enter into the agreement when throughput is high, since greatest net revenue is likely related to throughput volume. Elevators not used for long-term storage because of the nature of the business, such as a feed mill, generally have the least incentive to enter into the CCC storage agreement.

Number of Warehouses Approved Under the UGSA

Average *capacity* of warehouses under storage contracts not providing official weights and grades varies significantly by region. The magnitude of difference in size of elevators may not be as great as indicated in table 1 if the average *number* of structures per contract also varies significantly by region. It is important to note that these data are not the *number and average size* of grain elevator structures, but the *number and average approved capacity* under UGSA. A complete count of the warehouse structures would involve perusal of all records associated with each storage contract.

Capacity of Warehouses Approved Under the UGSA

Average capacity under the CCC agreement not furnishing official weights and grades is 547,000 bushels nationally. 5/ Smallest average capacity is in the Northern Plains, where approved capacity runs about one-half the national average; largest average capacity is in the South and East. The sharp contrast may be attributed to differences in farmers' marketing practices: onfarm storage is used for a high proportion of the crops in the Northern Plains, as evidenced by the ratio of farm stocks relative to production (table 3). There is a lesser need to build large storage structures in this situation. But because of differences in farmers' marketing practices (table 3), a smaller elevator in the Northern Plains may handle as much or more grain during a season as a larger elevator in another region.

The size distribution of contracted capacity under the UGSA with the ability to furnish official weights and grades shows less variability among regions than those without. Only the West deviates sharply from the average.

Average contracted storage capacity under the URSA shows marked variation by State (table 2). Structures used for rice storage are similar to other grain warehouses and serve similar functions. ASCS makes no distinction on the basis of ability to furnish official weights and grades in the case of rice dryers (elevators) under the URSA. Normally, rice moves directly from dryer to mill and all shipments are graded prior to sale, differing from other grains in this respect.

Assuming that the incidence of multi-elevator agreements is more or less uniform among size categories, ASCS data may be expanded to the universe of elevators derived earlier (table 4). These data appear to be reasonable approximations of a universe for which reliable statistics are not available.

^{5/} The latest available ASCS data (March 31, 1978) indicate that average capacity approved under the UGSA for this category has increased to 570,835 bushels, consistent with current expectations of Government, takeover of grain, a new UGSA schedule of rates, and statements made above about industry's expectations regarding grain inventories. Conclusions in this study would not be altered by using current UGSA data, and would cause comparisons with other data used in the study to cover different time periods.

INDUSTRY DATA ON GRAIN ELEVATORS

An Industry Survey

Following initial publication of the New Source Performance Standards (NSPS) (9) for particulate emissions by grain elevators, six State grain and feed associations surveyed their entire membership by mail questionnaire in May 1977. The purpose of the survey was to obtain information on location, storage capacity, throughput, number and capacity of receiving legs, total leg capacity, number of rail and truck loadout spouts, and number and rated capacity of grain dryers. This information was collected to assist in identifying facilities 6/ potentially subject to NSPS, and in evaluating the economic impact of NSPS. Since there was no followup of nonrespondents, these data are subject to the potential bias of any mail survey; that is, a greater than proportional response can be expected from those with the greatest direct interest in the subject. In addition, since not all elevator owners are members of the surveying organizations, part of the universe was not contacted; thus, generalizations of data analyses should be made with caution.

Coverage

Nearly 1,800 responses were received from the six States of Illinois, Iowa, Kansas, Minnesota, Nebraska, and Ohio (table 5). 7/ Depending upon the State, responses were received from 15 to nearly 40 percent of the number included in the SRS list of storage facilities. Response percentages would be higher based on grain elevators only. In general, response rate was good for a mail survey. It should be remembered, however, that this is a count of responses, and not a count of the number of elevators.

In some States, the percentage of storage capacity covered in the surveys was somewhat higher than the proportion of facilities included in the SRS list (table 6). However, Nebraska had the thinnest coverage in both cases, with about 15 percent of both numbers and capacity.

Location of Elevators

Over 70 percent of the respondents indicated that they were located in areas with a population of 1,500 or less; two-thirds of these were in rural areas (table 8). About 2 percent were located in an area inhabited by 25,500 or more people. In the low density population areas where a majority of the respondents are located, there are fewer sources of air pollution than is the case for many other industries.

There appears to be no correlation between population of the area where an elevator is located and its storage capacity (table 9). The smallest size class of elevators was reported in the largest population class, and the largest elevator class was reported in the rural areas.

 $[\]underline{6}$ / Facilities, as used here, refers to the definition in $(\underline{9})$ --"Identifiable pieces of process equipment or individual components which when taken together would comprise a source" of emission.

^{7/} A few questionnaires were received after analyses were begun and are not included in these results.

Selected Physical Characteristics of Elevators

Storage Capacity

Average storage capacity of respondents to the industry survey generally corresponded to averages of UGSA contracts (table 7). In the largest storage capacity category, however, respondents' capacity was much less than the average UGSA contract. The overall average of the surveys was around 135,000 bushels smaller than the average of the UGSA contracts. Large elevators which already have extensive dust control systems may not have felt a need to respond, or in some cases may not have been members of the State organizations.

Approximately 40 percent of the respondents reported detached storage capacity, representing about 35 percent of total capacity (table 10). Almost 63 percent of respondents in Iowa had detached storage facilities, over twice the ratio in Illinois and Ohio. The percentage of detached storage capacity decreases as size increases. Overall average capacity of respondents with detached storage facilities was about 15 percent greater than for those with only primary storage (tables 11 and 12). Nebraska respondents had the greatest percentage of detached storage capacity--54 percent. Respondents in the smallest category averaged almost three times as much detached storage capacity as those in the 2.5 and 5.0 million bushel category.

Throughput Ratios

Throughput ratios 8/ were highest in all six States for the smallest storage capacity category (table 13); however, Kansas, the predominant wheat State, had the lowest turnover rate, and Illinois, a major corn State, had the highest. Throughput ratios for the next five categories generally decline. This trend reversed itself for elevators with over 5 million bushels capacity, rising, in Ohio for example, to a ratio greater than for the smallest category.

Receiving Legs

Overall, the modal number of receiving legs is two for respondents (table 14). The average is 2.53 (table 15), with substantial differences in average number of receiving legs. Extreme variations are most likely the result of averages computed from a small number of respondents.

Loadout Spouts

In storage capacity categories, over 89 percent of Kansas respondents reported rail loadout spouts for storage capacity of 100,000 bushels or less, compared with 21 percent for Ohio. About one-half the respondents in the other States reported rail loadout spouts for that capacity. At the other end of the capacity spectrum, all respondents with over 5 million bushels storage reported both rail and truck loadout spouts.

The average number of truck and rail loadout spouts is generally greater as storage capacity increases (tables 21 and 22). Illinois respondents had the greatest average number of both rail and truck spouts, while Ohio had the lowest average number of rail spouts, and Kansas the lowest number of truck spouts. The modal number of

8/ A throughput ratio is the ratio of annual volume to storage capacity.

7

rail loadout spouts for all respondents was one; however, two loadout spouts was the mode for respondents in the 1.0 to 2.5 million bushel storage capacity category (table 23). The modal number of truck spouts was two for Illinois, Iowa, and Kansas; and one for Minnesota, Ohio, and Nebraska (table 24).

Dryers

At 94 percent, Iowa and Ohio had the highest percentages of respondents with grain dryers by storage capacity, while in Kansas, the predominant wheat State, only 65 percent of the respondents had dryers (table 25). Generally, the greater the storage capacity, the more likely respondents were to have dryers; in Minnesota, however, the few respondents in the largest capacity categories did not have dryers (tables 26 and 27). The average number of dryers increased as respondents' storage capacity increased, with an average of two dryers for respondents with storage capacity greater than 500,000 bushels. As number of dryers tended to increase with storage capacity, so did dryer capacities (tables 26-28).

OPERATING CONSIDERATIONS

The preceding information, while useful, provides an incomplete picture of the complexity of elevator operations. Depending on the size of the elevator, legs and conveyor belts often serve a multiplicity of uses. A leg or belt can be used for receiving, loadout, and conditioning. In larger elevators, some specialization of equipment use is likely. However, in some cases, specification of regulatory mechanisms can have in impact upon the productivity of individual elevators and, in turn, the grain marketing-transportation complex. For example, the proposed NSPS required a completely enclosed shed for dumping railcars. Such a control might have reduced the productivity of the car dump by requiring uncoupling of each car. Further, if the leg servicing the car dump was also used for other purposes, such as loadout or turning inventory, productivity of equipment not directly related to the original control point might be reduced. Analysis of the economic impact of such a proposal must thus look at the regulatory impact upon the entire elevator rather than at individual parts.

REGRESSION ANALYSIS TO PREDICT THROUGHPUT

It was proposed that the New Source Performance Standards be applied to individual firms on the basis of receiving leg capacity. A cutoff point was established whereby elevators with greater leg capacity would be subject to the standards, but smaller elevators would not. Throughput, the annual volume of grain handled by an elevator, is a proper measure of grain business activities, and in the case of standards regulating dust emissions, directly correlates with the quantity of dust generated (allowing for differences in type of grain).

Regression analysis of industry survey data was used to determine the relationship between throughput and the number of legs, leg size, storage capacity, number of rail loadout spouts, and number of truck loadout spouts. The purpose of this analysis was to determine if the annual volume of business (bushels) was related to physical characteristics of the elevator. The results do not demonstrate a strong relationship between throughput and any of the physical characteristics of respondents' operations (table 29). Storage capacity was the most reliable indicator, yet it explained less than 40 percent of the variability in throughput. Total leg capacity and largest receiving leg capacity explains 22 and 23 percent of throughput variability, respectively. The number of rail or truck loadout spouts has no relationship to throughput. These results are not surprising. Elevators are designed for the efficient handling and storage of bulk grain and are built to serve the objectives of the management and the needs of farmers in the local area. More important, management differs in its aggressiveness--two elevators, side by side and identical in all physical respects, will probably have differing annual volumes of business simply because of management.

Throughput differs by area of the country. Areas with a large proportion of onfarm storage need less storage and handling capacity than areas where farmers deliver a high proportion of the crop at harvest. Thus, for the same size elevator, an elevator in one area may have a lower annual throughput than one in another area. The data on throughput ratios (table 13) show that respondents in the various States did report differing average turnover ratios.

CONCLUSION

The universe of grain elevators must be defined in number and by type of operation to properly and accurately evaluate the impact of any situation having economic repercussions on grain elevators. Physical layout and business functions must likewise be defined before any regulations can be equitably applied.

Because of the physical differences among grain elevators, it is virtually impossible to use publicly available statistics to set blanket regulations having an equal impact on all such structures. Thus, a survey statistically designed to obtain the proper kind of data is needed.
