**“*AJAE* appendix for ‘Would you choose your preferred option? Comparing choice
and recoded ranking experiments”**

Alejandro Caparrós, José L. Oviedo, Pablo Campos

November 27, 2007

“Note: The material contained herein is supplementary to the article named in the title
and published in the American Journal of Agricultural Economics”

Differences between the *choices* and *first rankings* of each treatment

Table 1 shows the results of the comparison between the proportion of respondents that *chose* or *ranked first* a treatment (alternative) out of the 17 that we used in our experiment. The χ^2 -tests show that for 15 treatments we cannot reject the null hypothesis of statistically similar percentage of times a treatment is chosen/ranked first (at the 5% level) (table 1).

[Table 1]

Nested logit and random parameter logit with socioeconomic characteristics

In this section we present (i) a nested logit (NL) including socioeconomic characteristics in the election among branches and interacting with the attributes of the elemental alternatives and (ii) a random parameters logit (RPL) (Layton 2000) with socioeconomic characteristics interacting with the attributes. These models check if the results remain the same when we allow for heterogeneity. The RPL also relaxes the assumption of independence of the eight choices made by each respondent.

In the RPL we include interactions between the *ASC* and some socioeconomic variables. However, since the *ASC* captures the mean effect of the unobserved factors in the error term it is difficult to test hypothesis regarding this term (Blamey et al. 2000). As in the NL model without socioeconomic characteristics, *ASCs* for reforestation alternatives were not significant in the NL model with socioeconomic characteristics and are not included (see next section).

The socioeconomic characteristics (table 3 in the article) used in the branches in the NL and interacting with the *ASC* in the RPL are the family income (*INC*), the age

(*AGE*) of the respondent and a dummy variable (*CAD*) that takes value 1 if the respondent is from the *Cádiz* province, where the Alcornocales Natural Park (ANP) is located (value 0 otherwise). Two dummy variables interact with the attributes: (i) the variable *REA* takes value 1 if the main reason of the respondent for visiting the ANP was related with active tourism (hiking, biking, climbing) (value 0 otherwise); and (ii) the variable *SUS* takes value 1 if the respondent knows a close substitute to the ANP (value 0 otherwise). The remaining socioeconomic variables presented in table 3 of the article were not employed because of correlation problems.

We have estimated models (i) including all possible variables; (ii) including variables which were significant either in the choice or in the recoded ranking regressions; and (iii) including only the variables significant in both the choice and the recoded ranking regressions. We present in detail only the regressions for the models described in (ii) above, since they avoid unnecessary information from common non-significant variables and allow for potential socioeconomic differences. For the welfare measure analysis, we compare the models described in (iii) because they allow for a homogeneous comparison.

For comparing the parameter vectors in the RPL models we can only conduct a standard Likelihood Ratio test because the likelihood function in these models is not globally concave and quite erratic (Lusk and Schroeder 2004).

In table 2, we present the regression of the NL for the choice and the recoded ranking and the Likelihood Ratio test result. Most of the variables are significant in both models with the same sign and we cannot reject the hypothesis of equal parameter vectors. Although not shown in table 2, we also cannot reject the null hypothesis of the Likelihood Ratio test for the model with all possible variables (χ^2 (d. f. = 21) = 27.402)

and for the model only with the variables significant in both the choice and the recoded ranking (χ^2 (d. f. = 14) = 15.576).

Table 3 shows the welfare measures and the results of the comparison tests. As in the base models, most welfare measures are statistically equivalent, including the new ones derived from the interaction of the attributes and the socioeconomic variables.

[Table 2 and 3]

For the RPL model (table 4), the results of the comparison between models are fairly similar to the ones obtained in the NL. The standard Likelihood Ratio test cannot reject the null hypothesis (table 4). In table 5 we show the welfare measures and the results of the comparison tests for these models, which are similar to the obtained in the comparison of the NL models.

[Table 4 and 5]

Nested logit (NL) models with an alternative specific constant

In this section we present two additional NL models with an alternative specific constant (*ASC*) for reforestation alternatives. Table 6 shows the NL models without socioeconomic variables and table 7 the NL models with socioeconomic variables. Since the *ASCs* are not significant we did not include these models in the main text and did not perform additional comparison tests.

[Table 6 and 7]

Testing effects

In this section we present the statistical details of the models that try to detect the influence of different effects. We show the regressions, the Likelihood Ratio test and the welfare measures tests for the comparison between sub-samples that isolate respondents who could have been affected by a concrete effect. These tests are done only for the NL described in the article since the results of the comparison remains strongly similar irrespective of the specification used.

The models identifying “learning” and “fatigue” effects (called C4_L and C4_F respectively for the choice data and RC4_L and RC4_F for the recoded ranking data) show that all attributes are statistically significant at the 1% level with the expected sign (table 8). The Likelihood Ratio tests reported in table 9 do not reject the hypothesis of statistically equal parameter vectors in both comparisons. Table 9 also reports the Likelihood Ratio tests for the sub-sample models described below.

[Table 8 and 9]

The results for the welfare measures comparisons are found in table 10 for the C4_L and the RC4_L models and in table 11 for the C4_F and the RC4_F models. For the parametric measures, the t-tests that compare C4_L and RC4_L show little significant differences (only at the 10% level). For the bootstrapping results, the complete combinatorial tests show little significant differences in both cases.

[Table 10 and 11]

Using the four follow-up statements (see table 12) we created sub-samples for choice and for recoded ranking data and compare them for testing the effects referred in the article. For the first follow-up, we compared sub-samples made with respondents that scored it with 1, 2 or 3, detecting an “information” effect (models CQ₁ and RCQ₁). For the second follow-up, we compared sub-samples made with individuals that scored it with 3, 4 or 5, checking for a “difficulty” effect (models CQ₂ and RCQ₂). For the third

follow-up, we compared sub-samples made with those who scored it with 3, 4 or 5 checking an effect associated with the number of choice sets presented to each respondent (“choice sets” effect) (models CQ3 and RCQ3). For the fourth follow-up, we compared sub-samples made with those that scored this statement with 3, 4 or 5 checking for a “response effort” effect (models CQ4 and RCQ4). Table 12 shows the scores given to the follow-ups (from 1 (totally disagree) to 5 (totally agree)) and the χ^2 statistics for testing differences. In all cases we cannot reject the hypothesis of similar scores.

The results of the regressions estimated with the sub-samples made using the follow-ups are reported in table 13. The only difference with the regressions obtained using the whole samples is that the attribute *REC* in the RCQ1 model is only significant at the 10% level. However, we are not able to discern whether this is caused by the “information” effect or by the reduced observations of RCQ1 (732 observations), with the consequent decrease of its explanatory power. Nonetheless, this also happens in CQ1 (776 observations), where no decrease in explanatory power is observed.

[Table 12 and 13]

The Likelihood Ratio tests (see table 9; CQ1 versus RCQ1, CQ2 versus RCQ2, CQ3 versus RCQ3 and CQ4 versus RCQ4) state that in the models hypothetically affected by the “difficulty” effect (CQ2 versus RCQ2) H_B is rejected. This implies that the difference resides in the scale parameter and not in the taste parameters.

Table 14 shows the parametric and bootstrapping results of the comparison between the welfare measures of CQ1 and RCQ1 models. We found little differences and only in the complete combinatorial tests. Table 15 presents the same results for CQ2 and RCQ2 models, finding also little differences in the complete combinatorial tests and one in the parametric t-test but only at the 10% level.

[Table 14 and 15]

Tables 16 and 17 show the parametric and bootstrapping welfare measures comparisons for C_{Q3} and RC_{Q3} and for C_{Q4} and RC_{Q4} models respectively. We found that only the t-test and the complete combinatorial test yield some statistically significant difference and most of them at the 10% level.

[Table 16 and 17]

Thus, as in the comparison of the whole samples, there is almost no difference between the results of a choice and a recoded ranking when we test for the four effects analyzed with the follow-up statements.

Table 12. Respondent's Scores About the Valuation Exercise from 1 (totally disagree) to 5 (totally agree)

Follow-up statements	Choice		Ranking		χ^2 -test ^a
	sample		sample		
	Mean	N	Mean	N	
I correctly understood the information provided in the previous choices/rankings	4.30 (0.95)	429	4.37 (0.95)	429	-0.05 ^b
I had difficulties in stating my answers in the previous choices/rankings	2.10 (1.23)	429	2.07 (1.26)	429	14.08
The number of choices/rankings that I faced has been excessive	2.45 (1.44)	429	2.64 (1.48)	429	12.87
I thought more about my answers of the first four choices/rankings than about the last four choices/rankings	3.02 (1.59)	429	3.04 (1.59)	429	22.76

Note: Standard errors are shown in brackets; N: number of observations.

^a χ^2 with 16 degrees of freedom at the 5% level = 26.30 (the contingency table had five rows and five columns).

^b In this case, the χ^2 test cannot be fulfilled since at least one cell of the contingency matrix is equal to zero. The statistic showed is a *t-test* statistic for testing the difference between mean values (*t-test* statistic at the 5% level = 1.96).
