¹ This research report comes from the original master thesis work of H. Coles. See Coles, Heath. 1989. "Risk And Return Analysis Of Beef Feedlot Investments In Alberta." Master of Science Thesis, Department of Rural Economy, University of Alberta, Edmonton, Alberta.

² The authors are Professor of Agricultural Economics, Department of Rural Economy; Professor of Finance, Faculty of Business; and Research Assistant, Department of Rural Economy, respectively.

Acknowledgements

The authors are grateful for the technical advice provided by Dr. Gary Mathison, Department of Animal Science, and Dr. Wictor Adamowicz, Department of Rural Economy, both of the University of Alberta. Appreciation is also extended to Alberta Agriculture which was the source of various types of technical and economic data. This project would not have been possible without their support and particularly the financial support of Alberta Agriculture through its Farming for the Future program. Thanks is also extended to Tri-S-Farms Ltd. for the assistance that they provided on this project.

Abstract

The objectives of this study were to identify sources of risk facing an investor in beef feeder cattle, measure the returns and risk associated with this investment, and calculate a beta coefficient which can be used to evaluate investment opportunities in beef feedlots.

Analysis of the data indicated that the major source of risk in cattle feeding investments are attributable to market price risk. A breakdown of mean square error components and removal of non-price risk factors did not appreciably reduce variability.

The investor was assumed to purchase 100 head of cattle each month and place them on feed in a commercial feedlot for a finishing period of approximately 90 days. The returns on each lot of 100 head was calculated and compared to anticipated returns based upon prices predicted from the futures market data available at the time when the decision would have been made. This series of returns over the 156 month period was found to have a mean real annualized return of 6.32% with a root mean square error of 41.1%. Comparisons to stock market performance as revealed by the TSE 300 over the same period of time resulted in a beta value of 0.64.

An alternative strategy was developed under which the investor would invest in cattle when predicted cattle returns exceeded predicted 90 day treasury bill returns and invest in treasury bills otherwise. In this case a real annual return of 9.0% was realized with a mean square error of 34.2% and a beta value of 0.40.

I. INTRODUCTION

A. BACKGROUND

The beef industry has always been a major part of the agricultural economy in Alberta. Statistics for 1986³ showed that cattle and calves accounted for 29.3% of the total farm cash receipts with a dollar value of \$1,106,000,000. Wheat was the second highest with 13.7% of the total. Statistics also show that in 1986 there were 1,004,307 steers and heifers of Alberta origin slaughtered and as of July 1, 1986 there were 681,000 steers and heifers being fed for slaughter on Alberta farms.

A large number of these cattle are finished and marketed through commercial feedlots. With the large number of calves (1,067,000 in 1986) being produced in the province and with the development of custom feedlots which allow for "hands-off" involvement in the industry it would seem that an opportunity exists for off-farm investors to invest money into the industry if it compares favorably to other investments and if it fits well into a portfolio of investments.

Investment choices can be studied on the basis of two criteria; rate of return and variability of return or risk. Measuring rates of return, given data on the revenue and costs of an investment is straightforward. If all other factors are constant then choosing an investment is merely a matter of finding the most profitable one or in other words, the investment with the highest rate of return.

Unfortunately, this method of investment choice is highly simplistic and likely to produce disappointments when applied to real life conditions. In reality there is risk involved with each investment and an investor must make decisions as to the level of risk that he wishes to endure. Once this risk level is determined the investor must then choose the investment or portfolio of investments which will provide the highest rate of return and the investor must be able to evaluate the effect of an investment on his portfolio.

The measurement of risk first requires an understanding of the types and sources of risk which an investor faces. In the context of a beef feedlot investment there is both production and price risk to consider and the challenge is to develop a model which accurately incorporates and measures the risk which these factors contribute to the investment.

B. OBJECTIVES

The objectives of this research work are threefold. The first objective was to identify sources of risk facing an investor in beef feeder cattle. The second was to measure realized net returns and to measure the variation in these realized returns from predictions. The third objective was to evaluate beef feedlot investment opportunities and relate them to alternative investments.

³ See Alberta Agriculture Statistics, 1987.

II. THE CONCEPTUAL BACKGROUND

A. INVESTOR BEHAVIOR

Utility and consumer theory provides a framework which makes possible the assumption of rational behavior of a consumer in the marketplace. An investment decision, which is a decision to delay consumption over time, is one aspect of consumption theory and thus is covered by the same axioms of consumer behavior as other consumption decisions.⁴

The returns which accrue from an investment decision reflect two things. One is the time value of money which is the portion of returns equal to that of a riskless asset. The second is the risk premium associated with delaying consumption.⁵ Rational investors, while being interested in higher returns, are also considered to be risk averse. The level of risk premium associated with an investment is determined not by an individual's utility function but by the utility functions of all investors in the marketplace. Individual investors make investment choices based on the amount of risk involved and the risk premium being offered. Once a desirable level of risk is determined, a rational investor will always choose the investment at that risk level which offers the highest risk premium.

Therefore it is necessary to be able to measure risk and returns in evaluating investment alternatives.

B. MEASUREMENT OF RETURNS

A definition of net returns is given by the equation:

$$r = \Gamma - \Theta \quad (1)$$

where: r is the net dollar returns per period

Γ is the cash inflow per period

Θ is the cash outflow per period.

These returns are calculated for each time period being studied and can be refined to express returns in percentage terms as the internal rate of return whereby:

$$X_j = \frac{r_j}{\Theta_j} = \frac{(\Gamma_j - \Theta_j)}{\Theta_j} \quad (2)$$

where: X_j is the rate of returns

j is the time period.

Mean values for returns are calculated as follows using the returns for individual time periods:

$$\bar{X} = \frac{1}{n} \sum_{j=1}^n X_j \quad (3)$$

where: \bar{X} is the mean return

n is the number of time periods.

C. MEASUREMENT OF RISK

Risk measurement involves measuring the variation in returns. It compares observed values of a parameter with either the mean or predicted values of a parameter and calculates the variation.

Variance measures the dispersion of estimates about their mean value. It is measured as:

$$VAR = \frac{1}{(n-1)} \sum_{j=1}^n (X_j - \bar{X})^2 \quad (4)$$

⁴ Consult Varian (1978), Green (1976), Henderson and Quandt (1971), and Gravelle and Rees (1981) for a discussion on these axioms.

⁵ See Brealey et al (1986).

where: X_j is the observed value
 \bar{X} is the mean of the observed values
 $(n - 1)$ is the number of observations.

The term $(n - 1)$ is used rather than n because it is a sample of a population rather than the population itself. This measure assumes that the investor has no prior knowledge of future events. It can thus be considered to be a naive or simple measure of risk because the predictable portion of this variation is assumed to be zero and hence it overstates risk.

This equation can be broken down into its random and predictable components as follows:

$$(X_j - \bar{X})^2 = [(X_j - \hat{X}_j) + (\hat{X}_j - \bar{X})]^2 \quad (5)$$

where: $(X_j - \bar{X})^2$ is the total risk
 $(X_j - \hat{X}_j)$ is the random portion
 $(\hat{X}_j - \bar{X})$ is the predictable portion
 \hat{X}_j is the predicted value of the outcome.

Often there will be information available to the investor which may allow him to anticipate some of the variation which will accrue to an outcome. In cases such as this the predictable portion of variance is not zero and can be excluded from the risk measurement by using a predicted value for the outcome. Thus a situation arises where it is more appropriate to use a method of risk measurement which includes only the random portion of variance.

Mean square error (MSE) measures dispersion of results from the predicted value of the parameter. It is defined as:

$$MSE = \frac{1}{(n-1)} \sum_{j=1}^n (X_j - \hat{X}_j)^2 \quad (6)$$

D. BASIS RISK

The model designed for this project uses futures contract prices to determine predictions of slaughter prices for cattle. The risk arising from the use of futures contract prices comes from two sources: risk in the futures market itself and a second source of risk called basis risk.

Basis is defined as the difference between the futures contract price and the present cash price. For storable commodities such as grain the present cash price and futures price are related because the same expectations are used in determining both prices and basis is said to be a market determined value (Leuthold 1979).

Non-storable commodities such as beef cattle do not have a market determined basis but rather it is a residual between the present cash price and the futures price. The two prices are considered to be independent with cash prices being a function of current supply and demand conditions and futures prices being a function of expected supply and demand (Leuthold 1977, 1979).

The difference between basis risk and risk in the futures market can be explained in the following manner.

If an investor is in period t and wishes to predict the slaughter price in period $(t+3)$ then one method is to look at the price in period t of a futures contract deliverable at period $(t+3)$. The mean basis is the mean historical difference between prices at period t of futures contracts deliverable at period $(t+3)$ and slaughter cash prices at period $(t+3)$. Calculating the mean basis and subtracting it from the futures contract price provides an estimate of the cash price prediction for period $(t+3)$.

The variation which may eventually occur between the predicted cash price and the realized cash price comes first of all from variation in the realized price from the futures contract price, and secondly from variation in the realized basis from the mean basis.

A numerical example illustrates these two sources of variation. In order to simplify the example the exchange rate from Canadian to U.S. dollars is assumed to be constant.

If it is assumed that the futures contract price in period t for period $(t+3)$ is \$81 U.S. and the predicted exchange rate for period $(t+3)$ is \$.90 U.S. then the futures contract price is \$90 Can. If it is also assumed that the mean historical basis is \$7 Can. then the predicted slaughter price for period $(t+3)$ is $\$90 - \$7 = \$83$.

When period $(t+3)$ arrives the realized price is found to be \$79 which indicates that there was a total variation of \$4. This variation can be broken down into its components in the following manner.

It is necessary to observe the $(t+3)$ period futures contract price early in period $(t+3)$. If it is assumed to be \$78 U.S. then it will be \$86.67 Can.

The change in the futures contract is calculated to be $\$90 - \$86.67 = \$3.33$.

The basis at the time of delivery is $\$86.67 - \$79 = \$7.67$.

The change in the basis is $\$7.67 - \$7 = \$0.67$.

From this the total variation can be calculated from its components as $\$3.33 + \$0.67 = \$4$.

This research does not attempt to measure the amount of basis risk. However, it should be recognized that basis variability is a potential source of risk in the total risk of a feedlot investment. Literature on basis risk would suggest that it is present and is a significant part of the total variation in price.

Price et al (1979) did a study on basis variability where nearby basis is considered. They define nearby basis as the basis of the last eight weeks of a futures contract. They further divide basis by defining the delivery period as the period from zero to three weeks prior to delivery and the non-delivery period as being from four to eight weeks prior to delivery.

They concluded from their study that yearly variation existed in the basis and that there was variation with regard to delivery month. They found that variability of the basis was much narrower in the delivery period than in the non-delivery period and that location was not a source of difference in variability.

Vollink and Raikes (1977) determined that basis values for live cattle vary considerably during the delivery period. They felt that sources of basis variation were due to price expectations of speculators (40%) as well as the risk associated with delivery and arbitrage.

Garcia et al (1984) also looked at measuring basis for livestock markets. They did not assume that all basis is random and risky but rather that there is a systematic and non-systematic component. In this case they wanted to measure the non-systematic component. They stated that the variation in basis can vary over the contract life as new information becomes available due to several reasons:

1. arrival of new information is uncertain and unpredictable
2. similar information may have different effects depending on when it is received
3. as maturity approaches cash and futures prices are more closely tied and forecasts may also be more accurate
4. market location may affect the level of risk.

Their results suggest that there is significant variability in the random basis component and that there was not much evidence of lower levels of basis risk as contract maturity approached. They also found little difference in risk at different locations.

Overall, it would appear that basis risk exists and plays a significant role in the risk involved with estimating livestock returns.

E. RISK-RETURN TRADE-OFFS

As the returns on an investment increase the risk level increases as well. This means that the objectives of maximizing returns and minimizing risk are conflicting ones and some type of trade-off between the two must be made. In order to do this the investor must be able to analyze the types and effects of risk in an investment portfolio.

The theory of risk-return trade-off can be traced to Markowitz (1952) and the development of expected return-variance of return (EV) relationships and the theory that risk has two parts: unique or nonsystematic risk which is diversifiable and market or systematic risk which is non-diversifiable.⁶

An investor who can and wishes to diversify needs to be interested only in systematic risk and how a particular investment will affect the systematic risk in the portfolio.

F. BETA COEFFICIENT

Measuring the sensitivity of returns of an individual investment to market movements involves the measurement of what is known as a beta coefficient. The beta for a particular investment, X , is measured by:

$$\beta_x = \frac{COV(X, Y)}{\sigma_y^2} \quad (7)$$

where: β_x is the beta value for X

$COV(X, Y)$ is the covariance between returns to investment X and the market portfolio Y

σ_y^2 is the variance in the market portfolio.

With a well diversified portfolio which has eliminated all nonsystematic risk, a one percent shift in the market returns means a one percent shift in the portfolio returns and thus the portfolio has a beta value of one. An investment with a beta value equal to one is therefore assumed to have on average the same systematic volatility as a well diversified portfolio. A beta greater than one means that the investment exhibits more volatility than the market portfolio and will increase systematic risk when added to the portfolio. The opposite effect occurs with a beta value less than one.⁷

Because a portfolio investor is only interested in non-diversifiable risk, any risk premium on an investment will be related solely to systematic risk and the beta of that investment.

A riskless investment which does not contribute any additional risk to a portfolio will have no risk premium and a beta of zero while an investment which contributes the same amount of risk to a market portfolio as the portfolio already exhibits will have a beta of one and a risk premium equal to that of the market portfolio.

Since most investments are neither riskless nor do they exhibit characteristics the same as a market portfolio it becomes necessary to estimate beta values and/or risk premiums.

G. CAPITAL ASSET PRICING MODEL

Models for estimating the effects of systematic risk and calculating the risk premiums on an investment have been derived from the theoretical foundation outlined above and are used in risk analysis of investment opportunities and their effect on a market portfolio.

Markowitz (1959), Lintner (1965), and Sharpe (1963, 1964) developed the Capital Asset Pricing Model which, stated simply, says that in a competitive market the expected risk premium varies in direct proportion to beta⁸. CAPM is one of the most widely known and used methods of measuring beta coefficients. Its general form gives the following relationship:

$$r_r = r_f + \beta(r_m - r_f) \quad (8)$$

where: r_r is the required rate of return in equilibrium

r_f is the risk-free rate of return

β is the beta value.

⁶ For further reference on this see Markowitz (1952) or Brealey et al (1986), Pp. 135-136

⁷ See Brealey et al (1986), p. 158 and Collins and Barry (1986), p. 153

⁸ CAPM was developed by Sharpe (1964), Lintner (1965), and Jack Treynor in an unpublished article.

H. PREVIOUS WORK

There has been limited work done in the farm sector on measuring beta coefficients for agricultural commodities and assets. Most of the work that has been done has centered around the use of CAPM or the Single Index Portfolio Model as developed by Sharpe (1963, 1970).

The Single Index model provides a measure of risk for individual assets or enterprises that accounts for the combined effect of the asset's own variance as well as covariance with other assets. Unlike CAPM it does not require equilibrium in the market.

Collins and Barry (1986) used a Single Index approach to estimate beta coefficients for various cropping activities. These coefficients are for individual crops relative to the farm portfolio and are calculated based on variation in deflated net returns.

Turvey and Driver (1987) use a different approach in estimating beta coefficients for various agricultural commodities. They develop a Farm Sector CAPM which measures the beta coefficients relative to a farm portfolio. They note that equilibrium conditions exist within the farm sector for their model due to the method in which they construct their farm portfolio and therefore is consistent with CAPM theory. Their empirical results are based on measurement of returns using gross revenues which are not deflated.

Barry (1980) uses the CAPM approach to measure beta values and risk premiums for farm real estate by regressing a time series of excess returns, which are defined as being the returns above those received on a riskless asset, for individual assets against a time series of excess returns for a market portfolio:

$$R_{it} = \alpha_i + \beta_i R_{mt} + e_{it} \quad (9)$$

where: R_{it} is the excess rate of return on investment i

R_{mt} is the excess rate of return on the market portfolio

β_i is the beta value for investment i

e_{it} is the error term

The anticipated value for α_i is zero.

Mercier (1988) estimated beta coefficients for investments in Alberta farmland using CAPM and compared them to a market index.

A study done by Brown (1989) estimated mean annual returns and standard deviations for various cropping and livestock activities in Saskatchewan for the period from 1971 to 1987. Returns were calculated using annual investment periods and CAPM theory was used in estimating beta coefficients.

One of the enterprises was a beef feedlot investment and the results indicated a mean real annual return of 15.80% with a standard deviation of approximately 20%. The beta value, on a real basis, was -0.182.

This research project will apply the CAPM relationship to a beef feedlot investment alternative and a broadly diversified portfolio represented by the TSE 300 in order to develop a beta coefficient for the beef investment using MSE to measure errors in predicting returns.

III. METHODOLOGY

A. BEEF FEEDLOT INVESTMENT

A representative feedlot returns model will be specified and used to develop a time series of predicted and realized investments returns on cattle feeding over the period from January, 1973 to December, 1985. Realized returns are a blend of historical and simulated data on physical and market variables that affect cattle investment performance.

Returns are calculated based on a standardized cattle investment starting at the beginning of each month. A lot of 100 head of A1 steers are purchased at a weight of 380 kg and fed to a finished weight of 520 kg.

A prediction of net returns is formulated at the beginning of each investment period using information that is assumed to be available at that time. The realized rate of return is measured at the end of each investment.

A time series of investment errors is developed from the first two time series and used to evaluate the risk involved in these investments as well as forecast future cattle investment risk.

The basic form for rate of return is $\frac{REVENUE}{COST} - 1$.

The models used for predicted and realized returns are presented below in equations 10 and 11.

$$r = K_1 - [K_0 + F + Y + T + P_r + M] \quad (10)$$

$$\hat{r} = \hat{K}_1 - [K_0 + \hat{F} + \hat{Y} + \hat{T} + P_r + M] \quad (11)$$

where: r_a is the realized return

r_e is the predicted return

K_1 is the revenue from cattle sales

K_0 is the total initial cost of the feeder animals

F is the feed cost associated with finishing the animal

Y is the yardage cost associated with finishing the animal

T is the cost associated with disease incidence in the feedlot

P_r is the processing costs for the animals as they enter the feedlot

M is the marketing costs of the animals

and where a " ^ " above the term indicates that it is a predicted or forecasted amount as opposed to a known amount.

In these models the revenue component is:

$$(MARKET PRICE - GRADE DISCOUNT) \cdot (MARKET WEIGHT) \cdot (NO. OF HEAD) \cdot (1 - DEATH FACTOR)$$

The cost component is:

$$(FEEDER PRICE \cdot PURCHASE WEIGHT) + (FEED USED \cdot FEED PRICE) + (YARD COST \cdot DAYS FED) + (TREATMENT COST \cdot NO. OF HEAD) + (PROCESSING COST \cdot NO. OF HEAD) + (MARKET COST \cdot NO. OF HEAD)$$

The elements of these models are divided into three categories. The first category includes four of these elements (market weight, purchase weight, number of head, and death loss) which are included in the definition of the investment being considered.

The second category of elements are those which are considered to be determinate and include feeder price, yardage cost per day, most of feed cost, processing cost, and marketing cost. Historical time series provides information of feeder prices and feed prices while various empirical sources provide information on the other elements. These determinate elements are used in the development of both predicted and realized return time series.

The third category of elements are those which are considered stochastic. These include market price, grade discount, a small portion of feed cost, feed usage, days fed, and treatment costs. When developing the predicted returns time series the market price is estimated from market information available at the beginning of the feeding period while the non-market stochastic elements are estimated from mean historical results of various empirical sources.

The realized return series uses realized market and feed prices that are obtained from market information at the end of each feeding period while the other values for stochastic elements are obtained via simulation which in turn uses mean and variance data from empirical sources.

In several instances prices are not available as a time series but must be adjusted using a price index. Examples of this include feed hauling costs, feed processing costs, daily yardage fees, daily bedding costs, treatment costs per animal, processing costs per head, buyer's commission per head, and cattle hauling costs. These costs are adjusted using either a single price index or a combination of indices, depending on the variable involved.

The general formula to adjust prices using an index is as follows:

$$PRICE_p = \frac{INDEX_p}{INDEX_b} \cdot PRICE_b \quad (12)$$

where: $PRICE_p$ is the price in the period under consideration
 $PRICE_b$ is the price in the base period
 $INDEX_p$ is the index for the period under consideration
 $INDEX_b$ is the index for the base period.

If more than one index is used then each value is weighted by the proportion of the total price change the index represents.

1. REALIZED RETURNS

Equation 10 is the model for realized returns. It looks at the returns on a post-production or historical basis when all revenues, costs, and production variables are known. These returns are measured based on animals being kept for the amount of time required to gain 140 kg which was approximately 90 days and returns are defined as being the revenue remaining after all costs are subtracted off.

While production variables must be assigned a particular value for each time period it is recognized that a number of these variables do have a variance attached to them and will not be the same for each time period. As well, several equations do have random variables included in them and therefore covariance terms may also exist. It is necessary that these variance and covariance relationships be incorporated into the model and to accomplish this a simulation procedure is included when measuring realized returns. This simulation uses measures of mean and variance obtained from empirical sources for the variables in question and generates random values for these variables in order to reflect variation from the mean which can occur naturally. The result is an equation which provides a more accurate measure of variance because an individual observation can deviate from the mean without the mean value being affected, given a large enough sample. A further result is that historical returns are in fact not entirely historical because a random value is chosen based on historical measures of mean and variance. This is a trade-off which is necessary to reflect as accurately as possible the total variation in the model.

The following sections break down equation 10 for realized returns into its various components and includes an explanation of potential variance and covariance relationships which may exist within the equation.

a. REVENUE

The equation for realized revenue is as follows:

$$K_1 = W_1 \sum_{i=1}^N A_{1i} P_{1i} \quad (13)$$

where: i represents the grade

W_1 is the final sale weight of an animal

A_{1i} is the percentage of animals at each grade

P_{1i} represents the final price.

As indicated, the final sale weight, W_1 , is fixed and is therefore not a random variable.

It is necessary to determine if there is a covariance relationship occurring between the grade, A_{1i} , and final price, P_{1i} , that must be measured. In order for such a relationship to exist it is necessary that a change in one variable is at least partly a result of a change in the other variable.

First of all, can a change in price at a particular grade cause a shift in the percentage of animals marketed at that grade? Higher grades should receive higher prices but if the premium for receiving a higher grade is not large enough to justify the marginal costs associated with achieving that grade (or the reduced amount of product if it entails marketing animals at a lower weight) then producers will not always attempt to obtain this top grade.

However, for the purposes of this research it is assumed that producers do attempt to receive the highest grade possible and that there is a discount for animals that grade lower.

Secondly, can a shift in grade percentages for an individual feedlot affect the prices paid to individual grades? While there is always a discount in price as the grade of an animal decreases the situation can occur where the magnitude of the discount shifts. Assuming that the cause of this shift is due to changes in supply and demand factors when the animals are marketed, then it follows that in order for an individual feedlot to affect the magnitude of a discount between grades it would have to exert some effect on the supply of a particular grade of animal. While it can be argued that an individual feedlot's grades are unique and due to the managers' capabilities it is not reasonable to assume that this feedlot is enough to affect the supply characteristics of the entire market.

This provides the basis for the conclusion used in this study that there is no covariance relationship between the grading percentages for an individual feedlot and the price received for each grade of steer.

As previously mentioned the final weight, W_1 , is not a random variable and therefore no covariance exists between final weight and final price in this equation.

This indicates that the variation in revenue will arise from two sources when assuming a fixed final weight and these two sources are price and percentages of animals that fall into each grade.

The variation in price is accounted for through the use of a monthly weighted average price series for A1 and A2 steers sold Direct To Packer.⁹

The decision to use Direct To Packer prices hinged on the fact that almost all cattle are marketed in this manner and are therefore more accurate than Public Stockyard prices.¹⁰ The drawback to using this price series is that prices have only been reported since 1982 while Public Stockyard prices are available for the entire time period being studied. In order to overcome this problem, the two price series were compared for the time period from 1982 to 1985 inclusive and

⁹ Market prices for slaughter cattle were obtained from the Canada Livestock and Meat Trade Report which is compiled by Agriculture Canada.

¹⁰ Public Stockyard prices are obtained from the Livestock Market Review which is compiled by Statistics Canada.

the average price difference between the two price series was calculated. Direct To Packer prices were, on average, three percent higher and this premium was applied to Public Stockyard prices for 1973 through 1981 to arrive at Direct To Packer prices for this time period.

There are additional benefits to Direct To Packer sales besides increased sale price. There is no commission charge for handling and the animals are sold F.O.B. the feedlot so there are no hauling costs for sales. Both of these costs must be considered when selling through a stockyard.

When sold F.O.B. the feedlot there is a four percent shrink to account for anticipated weight loss during hauling. However, this shrinkage would occur to animals hauled to a stockyard as well.

In order to determine the discount which will occur due to variance in grades it was necessary to construct a distribution of real grade discounts and run a simulation. This is done by examining the marketings of a number of steer lots from a local feedlot to determine the discounts that accrued due to some animals receiving grades lower than A1.¹¹ The discounts are based on the marketing of cattle direct to packer. The data were limited to marketings of 20 animals or more because marketings of small groups of animals may reflect a different decision making process or marketing criterion than would be used when large lots of animals are marketed, as is assumed in this study.

This distribution of discounts is converted into real dollar values, grouped into ranges and then a weighted mean discount is calculated for each range based on the number of lots with each discount. The percentage of total lots in each range is then calculated to reflect the chance of each range being chosen through a random process. Using a uniform random number generator a simulation is done and a number is generated for each time period in the study. The discount used is the one which represents the range the random number falls into when chosen. Thus, a discount for each period is chosen randomly according to its frequency of occurrence from the original data. It is then converted to nominal dollars for that period.

The range of real discounts and their corresponding percentages are listed in Table 1 as follows;

TABLE 1 : RANGE AND PROPORTION OF GRADE DISCOUNTS USED TO CALCULATE REVENUE.			
DISCOUNT RANGE (\$/CWT)	WT. AVG. DISCOUNT (\$/CWT)	WT. AVG. DISCOUNT (\$/KG)	PROPORTION (%)
0	0	0	58
0.01-0.09	0.09	0.002	1
0.10-0.19	0.16	0.0035	9
0.20-0.29	0.24	0.0053	10
0.30-0.39	0.35	0.0077	7
0.40-0.49	0.44	0.0097	4
0.50-0.59	0.56	0.0123	3
0.60-0.69	0.63	0.0139	3
0.70-0.79	0.75	0.0165	3
0.90-0.99	0.96	0.0211	2

¹¹ Data were gathered from a feedlot using production and marketing techniques similar to this study for each group of steers marketed as to the price received for each grade and the number of animals that fall into each grade. Prices were reported on a rail grade basis and converted to a live weight basis using a dressing percentage of 57% that the feedlot indicated was normal for its operation.

The revised formula to calculate revenue is as follows:

$$K_1 = W_1 \cdot P_{1d} \quad (13.1)$$

where P_{1d} is the revised price for each month which is the A1 price less the discount which occurs due to some animals receiving lower grades.

The results of the calculations on 117 lots of cattle marketed for the 48 month period from January, 1984 to December, 1987 with 20 head or more indicate that there was a mean real discount of \$0.0035/kg.

During this period there were no discounts for animals within the A grade. The only discounts occurred when animals graded B1 or lower. This is indicative of the situation during the time period studied and is therefore a relevant and accurate measure of grade variability. Beginning in 1988 animals that graded A2 or lower were discounted from the A1 price. If a data series is examined that includes this time frame then this change would have to be incorporated.

The discount is subtracted from the price for A1 steers for each month of the time period to arrive at a net weighted average price received per kg for each month of the time period being studied.

The number of animals marketed is calculated by subtracting the death loss (0.4%) from the number of animals purchased. The study assumes that 100 animals are in the lot so 99.6 animals are marketed each month.

The price for each month as well as the final weight (520 kg) less a four percent shrink and number of cattle marketed are multiplied to arrive at the gross revenue for each lot of cattle.

b. FEEDER ANIMAL COST

The equation for calculating cost of feeder animals is as follows:

$$K_0 = W_0 \cdot P_0 \cdot Z_0 \quad (14)$$

where: W_0 is the purchase weight of animals

P_0 is the purchase price of feeders

Z_0 is the number of head purchased.

At the beginning of the feeding period, the weight of the animals being purchased is set at 380 kg and all feeder prices are for steers sold through Edmonton Public Stockyards.¹² Since W_0 is not a random variable, there is no covariance term between W_0 and P_0 .

c. FEED COST

The equations for calculating feed costs are as follows:

$$F = U \cdot P_f - S \cdot U \cdot 0.85 \quad (15)$$

$$U = G \cdot E \cdot H \quad (16)$$

where: F is the total feed costs per lot of animals

U is the total amount of feed required (t/lot)

P_f is the price of feed (\$/t)

S is the CBOP payment (\$/t) and is a constant

0.85 is the proportion of the total feed weight that is barley

E is the number of animals fed, including portions for animals that die or are culled, and is a constant

H is the feed conversion (feed/gain)

G is the total gain per animal.

Equations 15 and 16 are used in the estimation of feed costs for a group of animals.

¹² Data on prices of 380 kg feeder steers was obtained from Livestock Market Review.

1. FEED REQUIREMENTS

Equation 16 estimates the total amount of feed which will be required for the animals. It is a function of the total amount of gain, G , the total number of animals fed, E , and the predicted feed conversion, H , which by definition is the units of feed required to produce a unit of gain. The total gain is fixed so there is no covariance to consider with that term. It is assumed that the number of animals being fed are fixed.

Variation in feed requirements is one of the sources of risk associated with feeding cattle. This variation can arise from changes in the feed conversion, daily intake, or rate of gain and because these variables interact, a covariance relationship may exist between two or more of them. Failure to consider these variances will result in underestimation of the total risk. It is also critical that the variance surrounding a particular factor such as feed conversion be measured as accurately as possible.

The procedure used in this study was to estimate what levels of daily intake and average daily gain would be achieved using a certain ration and then calculate the corresponding feed conversion using a computer model which incorporates these production parameters.¹³ The levels of daily intake and average daily gain are estimated using relationships among these variables that have been developed through animal research trials for given sets of circumstances.¹⁴

The resulting estimation of feed conversion must have a standard deviation attached to it in order to calculate variation. This cannot be done directly as there is no variance attached to the estimate of feed conversion and no data to calculate a variance directly.

Animal science research trials which use similar rations fed to steers of similar size and type can be used to calculate a standard deviation for the feed conversion used in this study. The research data cited calculates means and standard deviations for daily intake, average daily gain, and feed conversion. It is assumed that the variation in one variable reflects the variation and covariation in the other variables as well because all three interact. This allows for the further assumption that the variance in feed conversion picks up all the relevant variance which will occur in feed requirements.

There are two methods of using the variance associated with feed conversion from the research trials to estimate variance associated with feed requirements in this study.

One method is to transfer the standard deviation values directly and use them as the standard deviation in this study. This approach has a major drawback because it assumes that even though the mean of a variable may change significantly, the variance will not change.

A second method is to assume that the coefficient of variation between the two means does not change.¹⁵ This will mean that while the ratio of the standard deviation to the mean does not change the actual variance will change.

The latter method was used because it was felt that as the mean level of feed conversion decreases its variance would decrease as well due to physiological factors involving the animal. Therefore, if standard deviation values were transferred directly the potential for error would be much greater than by using the coefficient of variation. Thus it is assumed for this study that as the mean level of feed conversion changes, the ratio of the standard deviation to the mean does not change.

13 Formulas for these calculations were obtained from National Research Council (1984).

14 Information on these relationships can be found in NRC tables for 1984

15 The coefficient of variation (C.V.) is defined as the ratio of the standard deviation to the arithmetic mean expressed as a percent. See Mason (1986), pp. 175-176.

It is important to note the consequences of this assumption being incorrect. If the coefficient of variation is not constant when it is assumed to be so and the actual variance levels do not change, then by moving to a lower mean the variance is understated at the new mean. The opposite effect occurs when moving to a higher mean. The exact direction and magnitude of error depends on the change in both coefficient of variation and actual variance when moving from one mean to another.

The original estimates of daily intake and feed conversion are based on the use of a ration containing 83.5% barley grain, 15% barley silage, and 1.5% minerals and vitamins on an as fed basis. Steers are fed from 380 to 520 kgs assuming an average daily gain of 1.48 kg/day will occur. Based on this a daily intake of 10.50 kgs of feed would be required and feed conversion would be 7.102 kgs of feed/kg of gain.

The source of data from which the standard deviations of feed conversion and ADG are obtained is unpublished data from Alberta Agriculture. It is based on 4200 steers of similar type to those assumed for this study which were finished in various lots from October of 1983 to December of 1984. The ration fed to these steers was also similar to the ration that is assumed to be fed for steers in this study.

The mean and standard deviation for feed conversion was calculated as 8.29 ± 0.39 kg on a dry matter basis. From this a C.V. of 4.7% is calculated.

Using the assumption of a constant C.V. described previously, the standard deviation for feed conversion can be calculated using this C.V. to be 0.33 kg on an as fed basis so that the mean and standard deviation for feed conversion used in this study is 7.102 ± 0.33 kg of feed per kg of gain.

This mean and standard deviation is now multiplied by the number of animals and total gain per animal to get a mean level of feed required and a standard deviation associated with it. Since both of these numbers are constant there is no variance attached to them and there is no covariance to consider.

The number of animals on feed is calculated from the number of animals originally purchased minus the death loss factor.¹⁶ A factor for the feed which the animals consume before they die is also included. It is assumed that animals which die consume 25% of the feed which would have been consumed over a full period in the lot. Assuming 100 animals are purchased for each lot during this study means that the number of animals fed is 99.7 if death loss is 0.4%.

The resulting mean feed requirement is 99,130 kg per lot with a standard deviation of 4,604 kg.

An assumption of the model is that the variance in feed conversion and hence feed requirements is normally distributed. At very low rates of gain the feed conversion rate will be extremely high and approach infinity as rate of gain approaches zero. At very high rates of gain the opposite effect occurs. However, when rate of gain falls within normal ranges the assumption of a normal distribution holds true. This allows for the incorporation of variance using a standard normal distribution of mean zero and variance one where a random value is chosen within this distribution and converted to a random variable within the distribution of feed requirements using the following formula:

$$\lambda = z \cdot \sigma + \mu \quad (17)$$

where: λ is the randomly generated value for a variable
 z is the Z-score value
 σ is the standard deviation of the variable in question
 μ is the mean of the variable.

¹⁶ Determination of death loss is discussed more fully under Disease Costs.

A simulation procedure to incorporate this variance is done for each month of data in the study. The resulting vector of feed requirements includes a measure of the variance of this parameter in the model.

The result is that a feed requirement is determined via simulation for each month based on the distribution of feed requirement values around the mean value.

2. TOTAL FEED COST

Equation 15 calculates total feed cost. The first term in the equation calculates gross feed costs which is a function of total feed required, U , and feed prices, P_f , with feed price being the price prior to any discounts for Crow Benefit Offset Program (CBOP) eligibility. CBOP will be discussed in further detail in the next section. The total feed required is a random variable in the sense that it is determined by feed conversion, H , which has a variance attached to it.

The existence of a covariance relationship between U and P_f depends on whether a change in one variable will affect the other. If we consider a situation where some factor such as weather conditions create a feed shortage in a region, then feed prices may rise due to lack of supply and therefore a covariance relationship will exist. Unfortunately, empirical measurement of the relationship is very difficult due to lack of available data. For the purposes of this study it is assumed that there are no localized supply restrictions and hence no covariance between feed requirements and the price of feed.

The second term of the equation deducts the benefits from CBOP which are constant on a per tonne basis and thus no covariance relationship exists.

The major source of variance associated with feed costs will come from changes in feed prices. The variance associated with production has been taken into account and the variance in feed prices is picked up in the following manner.

Feed costs are assumed to be paid at the beginning of the feeding period using prices for that month. A block of feed is purchased based on the predicted number of animals to be fed as well as the predicted rate of gain and feed conversion. An adjustment is made during the last month to account for any feed that is left over or any extra feed that is needed using prices for that month. The variation in the price of #1 feed barley is used as a proxy for the variation in feed costs.¹⁷ The assumption is made here that since barley accounts for a very large part of the ration it will be the source of almost all variation that occurs in feed costs. Therefore, other feed components are assumed to make up a constant proportion of feed costs and only vary as barley prices vary. A transportation cost of \$6.50 per tonne in 1988 dollars is added on for delivery to the feedlot. This figure is based on the assumption that the grain is hauled 65 km.¹⁸

As mentioned above the cost of other feed components is calculated as a percentage of the cost of barley and added on to give total feed costs. In the ration formulated for use in this study barley makes up 92.4% of the cost of the ration whereas all other components combine to make up 7.6%. Any variation in total feed costs will be due almost entirely to changes in barley prices and no significant amount of variation is lost due to this proxy. The total feed price will be calculated as:

$$P_f = P_b \cdot \frac{1}{\text{percent barley}} \quad (18)$$

¹⁷ Barley prices are obtained from Alberta Agriculture Statistics Branch and are prices for #1 feed barley delivered to country elevators in the Edmonton region. The data series is available back to January, 1975. Prices for 1973 and 1974 are calculated using a Grain Feed price index for Alberta.

¹⁸ See Custom Rates Survey Summary for Grain Harvesting Operations, Alberta Agriculture Statistics Branch 1988. Current prices are calculated using a Petroleum price index for Alberta that accounts for 33% of the change in cost and a Machinery and Motor Vehicle Maintenance price index which accounts for 67% of the change in cost.

where: P_b is the price of barley
percent barley is the percentage of the initial ration cost attributable to barley.
 In this study the equation reduces to:

$$P_f = P_b \cdot 1.082 \quad (18.1)$$

The cost of feed processing is included as an extra cost. A feed processing cost of \$0.241 per bushel (\$11.05 per tonne) in 1984 dollars is indexed to current dollars in each period using a farm input price index for supplies and services. This is converted to a price per kg and multiplied by the amount of barley and supplement used in each period to arrive at total feed processing costs per period. As indicated previously, 85% of the total feed is barley and supplement. This cost is added to other feed costs to arrive at a total feed cost.

This feed transformation factor of 1.082 is assumed to be constant and the consequences of this assumption are important to note. Under this condition the ration will not change regardless of the price of the different inputs. For instance, if the price of barley increases it cannot be substituted with another input.

In an area where alternative feed energy sources are not readily available this assumption may be valid. However, if alternative energy sources exist such as cull potatoes then it may not be possible to make this assumption. However, for the purposes of this study it is assumed that ration components are constant.

Total feed costs are then calculated by multiplying total feed requirements by the price of feed and subtracting off any subsidy payments that are received.

3. STABILIZATION AND SUBSIDIES

Major stabilization and/or subsidy programs can have a significant effect on net returns to producers and can affect risk since they may provide minimum price guarantees. Therefore it is necessary to include the benefits and costs from these programs in the model. It is not possible nor is it practical to attempt to include all stabilization and/or subsidy programs in the model but the major ones are taken into consideration.

The Crow Benefit Offset Program is the only revenue supplementing program considered in this paper. This program was set up and went into effect as of September 1, 1985. Its purpose is to offset distortions in feed grain prices between Western and Eastern Canada that were brought about by Feed Freight Assistance programs for Eastern producers. The program applies to both home-grown and purchased grain. Maximum limits for eligibility are set at six kg of grain/kg of gain for steers that weigh 318-454 kgs and seven kg of grain/kg of gain for steers weighing over 454 kgs. The rate of payment was \$21/t from September 1, 1985 until July 1, 1987 and \$13/t after July 1, 1987.

Producers receive the discount when they purchase the feed by presenting certificates to the seller who can then redeem them for payment. Therefore, the benefits from this program are shown in the model as a direct and immediate reduction in feed costs¹⁹.

A second program that is not considered in this model but which is worthy of discussion is the National Tripartite Stabilization Beef Program. This program was set up beginning in July of 1986 to provide minimum price guarantees to slaughter cattle producers. There are similar programs available to cow-calf and backgrounding beef producers and participation in all of the programs is voluntary. This program uses a formula based on past five year average prices for each quarter and feeder prices to calculate the minimum price for each quarter. Premiums are paid equally by the producer, the provincial government, and the federal government. It applies to animals marketed over 1000 lb. that have been owned at least 60 days.

¹⁹ Information on this program is available through CBOP office of Alberta Agriculture in Edmonton.

In July, 1986 the premium was \$6.60/head and this increased to \$7.40/head on July 1, 1987. There was an initial start-up payment of \$13.20 for the second quarter of 1986 as an incentive for enrollment and payments have been made for the fourth quarter of 1987 as well as in several quarters for 1988²⁰.

This program was not included in this model because it was not in effect during the time period measured. However, it has the potential to greatly affect the risk and return to beef feedlot investment since it reduces the variance which can occur on the lower end of the distribution due to the minimum price guarantee.

d. YARDAGE COST

The equation for total yardage costs is as follows:

$$Y = \frac{140}{D} \cdot J \cdot E + \frac{140}{D} \cdot B \cdot E \cdot O \quad (19)$$

where: Y is the yardage costs per lot
 J is the yardage cost per head per day
 B is the bedding cost per head per day
 E is the number of animals fed
 O is the straw used per head per day
 D is the average daily gain
 $\frac{140}{D}$ is the days on feed.

Yardage costs vary substantially from operation to operation because there are differences in which types of costs are included. Yardage costs used in this study are made up of yardage charges per day, which include book-keeping and general maintenance, and bedding costs per day. They are based on figures obtained from the 1987 Custom Rate Survey for Livestock Operations published by Alberta Agriculture. Figures are adjusted to reflect current dollars for each period using a Farm Input Price Index. Bedding costs are assumed to be \$0.04/head/day in 1987 and the index used is to adjust this cost is legume and grass production costs. Yardage fees are assumed to be \$0.15/head/day in 1987 dollars and the index used to adjust this cost is supplies and services in Western Canada. The portion of costs relating to bedding assumes straw is used at a rate of 0.91 kg/head/day and that it is constant and does not vary.

One source of variation in yardage costs is the number of days required to raise the animals to a finished weight. This will depend on the average daily gain achieved which, as was stated previously, has a variance attached to it. Therefore, it is necessary to determine the variance around this average daily gain to take full account of the risk associated with yardage costs.

The method used to calculate variance around the daily gain used in this study is similar to that used to determine variance around feed conversion where it is assumed that as the mean of ADG changes the standard deviation does not remain constant but rather the ratio of the standard deviation to the mean is constant. A mean ADG of 1.17 kg was obtained from the sample data with a standard deviation of 0.15 kg. From this a C.V. of 12.82% is determined. In this study an ADG of 1.48 kg is used and when the same C.V. is assumed as with the other study a standard deviation of 0.19 kg is obtained.

The variance surrounding ADG is incorporated using the normal distribution and simulation exercise as outlined for feed requirement variance. The result is that an ADG is determined via simulation for each month based on the distribution of ADG which reflects the variance around the mean value.

²⁰ Information on this program is available through Alberta Agriculture or Agriculture Canada.

Yardage fees are assumed to be paid at the beginning of the feeding period using a discount rate to convert these fees to period one dollars. The rate used will be the prime interest rate and it is assumed that yardage fees would be paid on a monthly basis.

e. DISEASE COST

The equations for calculating treatment costs are as follows:

$$T = Z_0 \cdot V + I \quad (20)$$

$$I = K_0 \cdot 0.01 \quad (21)$$

where: T is the total treatment cost per lot
 Z_0 is the number of animals treated
 V is the treatment cost per animal
 I is the Indemnity Trust Program premium.

One of the factors which has a significant effect on returns is disease. A major difficulty in attempting to measure the effect of death loss and sickness on the risk involved with feedlot investments is the lack of time series data which analyses this aspect of management. It was not possible to locate data which provided a measure of the variance in death loss and treatment costs for different lots of yearling steers over a long period of time. It was therefore necessary to use industry estimates and some cross-sectional data which does provide some estimate of the variables.

While it is recognized that these data are not ideal for this particular situation, it is felt that they do provide a relatively high degree of accuracy in estimating death loss and treatment costs.

In this study disease costs are dealt with in three categories.

1. DEATH LOSS

The first category is the actual death loss which occurs in the feedlot. An average figure of 0.6% is determined based on figures received from Alberta Agriculture and discussions with veterinarians. For the purpose of this study it is lowered to 0.4% to reflect benefits received from death loss assistance programs.

The Livestock Indemnity Trust Program is run by the Feeders Associations of Alberta²¹ to assist producers in limiting financial losses due to feedlot deaths. There are two programs available. Plan C provides coverage at a cost for premiums of one percent with a deductible of two percent and a payout value of 90% of the average value of the purchase price of the feeders. Plan D has a premium of 0.5%, a deductible of five percent, and a payout of 100% of the purchase price.

The deductibles are one time deductibles based on the total value of the animals purchased and is taken off the first claim. If the deductible exceeds the claim then the remaining portion is carried forward to the next claim.

Plan C was chosen to be used in this study. Since the rate of death loss is set at 0.4% there will not be any payouts under this program to the investor. However, it is common that feedlots with low rates of death loss make use of this program as it does provide protection against heavy losses due to death.

This program serves the purpose of reducing the variance in returns due to death loss that cattle feeders endure. Since a set rate of 0.4% is used in this study all variance is assumed away. However, in reality there is some potential variance and this program reduces it to a lesser amount.

²¹ This program is available through most but not all Feeders Associations of Alberta.

Since these programs have a deductible attached to them and since average figures are used for death loss, it is not possible to measure the benefits of this program which accrue when serious death loss occurs. Consequently, the average death loss rate is lowered by 0.2% in order to account for these benefits in measuring returns.

It is recognized that this method may result in an understatement of variance. However, lack of suitable data necessitates its use.

The animals that die are included as a reduction in the ending revenue and show up as a reduction in W_1 . Animals are assumed to die one quarter of the way into the production period. Therefore, animals that die incur 25% of the costs required to keep the animal for the full feeding period (i.e. feed costs and yardage costs).

2. CULLING DUE TO CHRONIC ILLNESS

The second category is animals that are chronically sick and must be culled out. Although few data are available on the number of yearling steers which fall into this category, all people consulted agreed that the number is extremely low and that rarely does an animal get culled at this stage of growth. Therefore it is assumed that for this study there are no animals culled.

3. TREATMENT COSTS

The third category to consider is treatment costs. A treatment cost per animal is determined and used to calculate total treatment costs per lot. Church and Radostits (1981) estimated treatment costs in feedlots to be \$6.94 per head received by the feedlot with a standard deviation of \$2.25 expressed in July, 1978 dollars based on 249,144 animals studied. This cost and variance is converted to current dollars for each time period using the Farm Input Price Index. These two figures provide an estimate for total treatment costs as it is calculated in equation 10. The standard deviation is used to calculate the effect of variance in treatment costs on the overall risk in the feedlot investment using the same simulation techniques that which was used for variance in feed requirements and ADG.

Since the animals lost to death or chronic sickness are included as animals not sold, the only actual costs in this category will be the treatment costs which are paid at end of the feeding period.

f. PROCESSING COSTS

The equation for processing costs is as follows:

$$P_r = Z_o \cdot P_p \quad (22)$$

where: P_r is the total processing costs
 Z_o is the number of animals purchased
 P_p is the processing costs per animal.

Processing costs are those costs associated with getting the animal ready to enter the feedlot and includes items such as growth implants and vaccines. This is not a random variable but rather is a known cost. It is adjusted to reflect current dollars through de-indexing with the Farm Input Price Index for supplies and services in Western Canada. The processing cost in June, 1987 dollars is \$2.75 with \$1.25 being delegated for implants, \$1.00 for vaccination, and \$0.50 for eartags as determined through consultation with Farm Management Specialists at Alberta Agriculture.

g. MARKETING COSTS

The equation for marketing costs is as follows:

$$M = Z_o \cdot Q_o + W_o \cdot L_o \quad (23)$$

where: M is the total marketing cost per lot
 Z_0 is the number of animals purchased
 Q_0 is the buyer's commission for purchasing animals (\$/hd.)
 W_0 is the purchase weight of the animals
 L_0 are the trucking costs for purchasing animals.

There are several charges to consider when buying and selling cattle. In most cases cattle buyers are hired to purchase cattle for the investor and are paid on a per head basis. Transportation costs for getting cattle to the feedlot are calculated as being a certain amount per loaded mile. Since cattle are sold F.O.B. the feedlot there are no charges for selling cattle or costs for trucking them.

In this study a buyer's charge of \$5/hd. in 1988 dollars is used based on discussions with cattle buyers in the Edmonton region. This is adjusted to reflect current dollars using the supplies and services index.

In order to calculate trucking costs assumptions must be made as to the distance that cattle are hauled to the feedlot. It is assumed that the cattle are hauled 210 km when being hauled to the feedlot. The rates for trucking are taken from the 1987 Custom Rates Survey for Livestock Operations and are set at \$1.25/loaded km in 1987 dollars using a truck with a capacity of 10,900 kg. Trucking rates are converted to current dollars using the Farm Input Price Index for fuel (33%) and motor vehicle maintenance (67%).

h. NET RETURNS

The calculation of the various revenue and cost categories then allows for the measurement of net returns using equation 10.

All cost figures are expressed in period zero dollars while revenue is expressed in period three dollars. Costs are converted to period zero dollars using a present value formula set up as follows:

$$PV_0 = C_0 + \frac{(C_1)}{(1+r_d)} + \frac{(C_2)}{(1+r_d)^2} + \frac{(C_3)}{(1+r_d)^3} \quad (24)$$

where: PV_0 are the total costs in period zero
 C are the costs paid out in each designated period
 r_d is the discount rate.²²

In this case a nominal discount rate is used and is calculated as:

$$r_d = r_p + \Omega \quad (25)$$

where: r_p is the prime interest rate
 Ω is the rate charged above prime.²³

Note that the decision to use a discount rate above prime assumes that the investor is borrowing funds to make the investment. If it was assumed that the investor was in a lending position then it would be necessary to use a rate below prime to reflect the return received on money being loaned.

Net returns are measured by subtracting all costs from revenue. The effects of inflation between time periods is removed using the general C.P.I. for Canada. This ensures that all dollars are in real terms and allows for comparison between time periods.

²² See Brealey et al (1986). P. 28.

²³ The prime interest rate is obtained from Cansim and is the Chartered Bank Prime Business Loan Rate.

Returns are also expressed as a proportion per time period using the following formula:

$$\frac{\text{ending cashflow}}{\text{beginning cashflow}} - 1 \quad (26)$$

2. PREDICTED RETURNS

Equation 11 is a model for calculating predicted returns. This equation uses realized values for parameters that are known and estimates for the variables which are not known. The theory behind the structure of the equation (such as elimination of covariance terms) is similar to equation 10. The primary difference lies in the source of data.

Whereas equation 10 used historical values and their historical means and variances to arrive at values for the variables, equation 11 uses futures prices and predicted values for parameters where the precise values are not known. In most cases the predicted value used is the mean value that was calculated. Variances are not incorporated into this equation since it is measuring predicted values.

a. PREDICTED REVENUE

The equation for predicted revenue is as follows:

$$\hat{R}_1 = W_1 \cdot \hat{P}_{1d} \quad (27)$$

The predicted final price, \hat{P}_1 , can be determined from one of several sources. One method is to take it as a function of the futures price applicable to when the cattle are sold less the mean discount for grades. Since there is no Canadian futures market, the futures prices are monthly weighted averages of live beef cattle futures taken from the Chicago Mercantile Exchange in American dollars and must be converted to Canadian dollars using exchange rates. The futures market for exchange rates is used to do this conversion rather the current exchange rates at the beginning of the feeding period because it gives the most accurate forecast of what the rates will be at the time of sale. Future exchange rates are based on 90 day spot exchange rates obtained from the Cansim data base.

In order to account for differences between Edmonton and Chicago prices due to basis it was necessary to subtract the predicted basis for each time period from the Chicago price. Predicted values are obtained from data for the current time period rather than historical time periods to reflect investor expectations.

The real basis values for each time period were calculated and were tested for time trends and seasonality to arrive at adjusted predictions of basis values for each time period. Appendix A provides a complete discussion of how the predicted basis values were determined.

A second method of forecasting final price is to use the futures price on a particular date during the month rather than a monthly average. The same procedure would be used to convert to Edmonton prices.

A third method of estimation would be to use the current cash price in the month the animals are purchased as an estimate of final price.

A MSE comparison of the price series data being considered in this study similar to that done by Leuthold (1977) showed that lagged cash prices had a slightly smaller MSE (0.0187) than either monthly weighted average futures prices (0.0196) or a futures price for a particular day of the month (0.0207). There is little difference in the values and when a comparison was done between monthly futures and lagged cash prices it was discovered that cash prices on average had an error of \$ 0.02/kg from realized prices while there was virtually no error when using monthly futures prices. Based on this it was decided that monthly futures prices would be used as the predicted sale price for the animals.

b. FEEDER ANIMAL COST

The values for initial weight, W_0 , and initial price, P_0 , are known when the cattle are purchased.

c. PREDICTED FEED COSTS

The equation for predicted feed costs is as follows:

$$\hat{F} = \hat{D} \cdot P_f - S \cdot \hat{D} \quad (28)$$

$$\hat{D} = G \cdot \hat{E} \cdot \hat{H} \quad (29)$$

Predicted feed costs are calculated based on the predicted level of feed conversion being estimated which in this case is its mean value. Again, this differs from equation 10 where variances for each variable are used to calculate an assigned value which takes production risk into account. Since feed costs are paid at the beginning of the feeding period the price of feed is known. The number of animals fed is fixed and is based on predicted levels of death loss and the length of time the animals are in the feedlot before they die. Both estimates are the same as for realized returns. The CBOP payment is known and is the same as for equation 10.

d. PREDICTED YARDAGE COSTS

The equation to estimate yardage costs is as follows:

$$\hat{Y} = \frac{140}{\hat{D}} \cdot J \cdot E + \frac{140}{\hat{D}} \cdot B \cdot E \cdot O \quad (30)$$

Yardage costs for this equation are calculated based on the yardage and bedding costs per day being known in advance and the number of days being a function of the predicted rate of gain. The number of animals is also estimated based on predicted death loss for steers during the feeding period. Since the death loss is assumed to be set at 0.4% then this number is assumed to be known.

e. PREDICTED TREATMENT COSTS

The equation to estimate predicted treatment costs is as follows:

$$T = Z_0 \cdot \hat{V} + I \quad (31)$$

Estimates for death loss and disease costs for this equation are the same as in equation 10 except that treatment costs use a predicted value and do not have a variance attached to them. The I.T.P. premiums are the same as for equation 10 as they are known as soon as the animals are purchased.

f. PREDICTED PROCESSING COSTS

The equation for estimating processing costs is as follows:

$$P_r = Z_0 \cdot P_p \quad (32)$$

Since the costs are incurred almost immediately they are assumed to be known with certainty.

g. MARKETING COSTS

The equation for estimating marketing costs is as follows:

$$M = Z_0 \cdot Q_0 + W_0 \cdot L_0 \quad (33)$$

Costs of buying and trucking purchased animals are estimated based on the number of animals and the costs being known beforehand which is similar to equation 10.

h. PREDICTED NET RETURNS

The calculation of predicted net returns in equation 11 is similar to realized returns in equation 10. All costs are expressed in period zero dollars while revenue is in period three dollars. Discount rates are in nominal terms.

Nominal returns were then converted to real returns using the CPI which is a general index. While the use of a predicted deflator is more conceptually correct, it would require that covariance relationships between the predicted return and predicted inflation rate be measurable. Since this is not the case it is more accurate to use a known inflation rate. Empirically, there is very little difference since the time period for the investment is only three months and the amount of error in predicting inflation rates would be very small.

The use of this method also allows for the assumption that T-bills are riskless.

B. DIVERSIFIED PORTFOLIO INVESTMENT

The measurement of a beta value for an investment requires that the variance in returns for that investment be compared to the variance of returns in a diversified portfolio of investments. In this case the diversified portfolio is represented by the TSE 300 index. The procedure for measuring returns is similar to that used for the beef investment where realized and predicted returns are measured for each period and the variance is calculated.

1. REALIZED RETURNS

A TSE 300 Total Returns index is used to measure realized returns to a diversified portfolio for the period of January, 1973 to December, 1985. The formula for measuring nominal returns is:

$$r_n = \frac{c_t}{c_{t-3}} - 1 \quad (34)$$

where: r_n is the nominal rate of return

c_t is the Total Returns Index for month three of each investment period

c_{t-3} is the Total Returns Index for month zero of each investment period.

Nominal rates of return are converted to real rates of return to allow for comparison of different investment periods.

$$r_r = \frac{(1+r_n)}{(p_t/p_{t-3})} - 1 \quad (35)$$

where: r_r is the real rate of return

p_t is the CPI for month three of each investment period

p_{t-3} is the CPI for month zero of each investment period.

2. PREDICTED RETURNS

The predicted rate of return on a diversified portfolio of investments is measured by calculating the mean of the realized time series of returns for both nominal and real values. The investor does not know what the variance on the investments will be but does know the historical mean and can use this knowledge to form his predictions of what future returns will be. The realized time series of returns for the period being studied (in this case 1973-1985) is used in calculating the mean rather than historical data in order to reflect the investor's predictions of what would happen during the period. The purpose in doing this is to eliminate naive variation.

This differs from the beef investment where the investor bases predictions on his predicted values for a defined series of events and parameters such as feed conversion or ADG.

C. ANALYSIS

The procedure outlined above provides two models which calculate predicted returns and realized returns on a monthly basis for the time period specified. These models for predicted and realized returns allow for use of the Mean Square Error approach which is used to measure variation in realized returns from predicted returns with variance of the beef investment, σ_x^2 , being calculated as outlined in Intriligator (1978).

$$\sigma_x^2 = \frac{1}{(n-1)} \sum_{j=1}^n (X_j - \hat{X}_j)^2 \quad (36)$$

where X_j is the realized or observed return on the beef investment and \hat{X}_j is the predicted return on the investment.

The variance on the market portfolio, σ_y^2 , is calculated in the same manner where:

$$\sigma_y^2 = \frac{1}{(n-1)} \sum_{j=1}^n (Y_j - \hat{Y}_j)^2 \quad (37)$$

The market portfolio used in this research is the TSE 300 Index.

The covariance between X and Y is measured using the following formula:

$$COV(X, Y) = \frac{1}{(n-1)} \sum_{j=1}^n (X_j - \hat{X}_j)(Y_j - \hat{Y}_j) \quad (38)$$

This then allows for the calculation of the beta coefficient for beef, β_x , as follows:

$$\beta_x = \frac{COV(X, Y)}{\sigma_y^2} \quad (39)$$

The correlation coefficient can be used to calculate the systematic and non-systematic components of risk. The correlation coefficient is defined as:

$$\rho_{x,y} = \frac{COV(X, Y)}{\sigma_x \cdot \sigma_y} \quad (40)$$

The two components of risk are then measured as follows:²⁴

$$\text{systematic: } \rho_{x,y} \sigma_x \quad (41)$$

$$\text{non-systematic: } (1 - \rho_{x,y}) \sigma_x \quad (42)$$

²⁴ See Levy and Sarnat (1982), pp. 299-301 or Turvey and Driver (1987), p. 391.

IV. ANALYSIS AND RESULTS

This chapter is broken down into four sections. The first section summarizes results from the beef feedlot investment and compares it to the market portfolio.

The second section discusses the results for various investment alternatives considered in the study.

Section 3 discusses the sources of risk in the model and their effects on total risk.

Section 4 looks at tests done for autocorrelation in returns and error terms.

A. BEEF FEEDLOT INVESTMENT

These results reflect an investment alternative where a 100 head lot of heavy feeder steers are purchased each month over a 13 year period from 1973 to 1985, placed on a custom feedlot, and fed to a slaughter weight using a barley-based finishing ration. The animals are purchased at a weight of 380 kg and fed to a weight of 520 kg over a time period of approximately 90 days.

Appendix D lists the realized returns on a beef feedlot investment for each month from January, 1973 to December, 1985. Returns are expressed as percentages and are on an annual basis. Quarterly returns are converted to an annual basis multiplying by four. The mean real annual return over this period was 6.32%. A graphical description of the movement in realized returns over this period is provided by Figure 1.

Appendix E lists the realized returns on the market portfolio, represented by the TSE 300 Total Returns Index, for each month from January, 1973 to December, 1985 as well as the realized returns on 90 day T-bills for the same period. The mean real annual returns on the market portfolio was 4.65% while the mean annual return on T-bills was 1.41%. Figure 2 shows the movement in realized market returns over this period. Figure 3 shows the movement in T-bill returns over this period.

Table 2 summarizes the risk and return measurements for the beef feedlot investment alternative and the diversified portfolio.

	MEAN RLZED RETURN (%)	MSE	ROOT MSE (%)	BETA B	CORR. COEFF $r_{(x,y)}$	SYS. RISK (%)	NON SYS. RISK (%)
FEEDLOT	6.32	1690.2	41.1	0.64	0.59	24.2	16.9
PTFOL.	4.65	1417.1	37.6	1.00	1.00	37.6	0.0

The results show that for the beef feedlot investment the average annual returns are 6.32% and have a root mean square error of 41.1%. This alternative provides a higher return than the diversified portfolio which has a mean return of 4.65% but it also has a higher level of risk as the root MSE on the portfolio is 37.6%. This is consistent with theory which states that higher levels of risk require higher returns to compensate for this risk.

Table 2 lists the beta coefficients for the beef feedlot investment and the market portfolio. The market portfolio will have a beta of one which is the average beta of all securities or investments in the portfolio. The feedlot investment has a beta of 0.64 which indicates that the beef feedlot investment's systematic risk is 64% of the market systematic risk and that the beef investment is less affected by market risk movements than the market portfolio.

A one percent movement in market risk will mean a 0.64% movement in the risk of the beef investment. This investment will decrease the beta of the portfolio if added to it and increase returns as well.

The calculation of a correlation coefficient between the total risk on an investment and the risk on a market portfolio allows for measurement of the systematic and nonsystematic proportions of total risk.

The market portfolio, since it is assumed to be totally diversified, has a correlation coefficient of one and all of its risk is systematic.

The feedlot investment is shown to have systematic risk of 24.2% and nonsystematic risk of 16.9%. On a proportional basis, this shows that nonsystematic risk makes up 41.1% of the total risk in the investment.

These results allow for interesting comparisons with other studies that were outlined in the literature review.

The study by Brown (1989) covering approximately the same time period indicated real net returns much higher than those obtained in this study (15.80% as opposed to 6.32%) and risk levels much lower (20% as opposed to 41%). While the exact method of calculation from Brown's study was not available it seems unlikely that real net returns would be this high over a 15 year period and it seems equally unlikely that returns between Alberta and Saskatchewan would vary this much.

The beta value which Brown calculated was also much lower than for this study (-0.182 as opposed to 0.64). Part of the reason for this might be the much lower overall risk levels calculated and the possibility of the level of systematic risk being underestimated.

Turvey and Driver (1987) also calculated a beta value for a beef feedlot investment but it was based on a farm portfolio rather than a market portfolio. The applications of this beta value are thus limited to questions of diversification within agriculture and their conclusion (their beta value was 0.91) indicated that diversifying within agriculture would be of little use for beef. It does not indicate the effects of beef investments on a more general portfolio.

The beta calculated here (0.64) indicates that there are possible benefits to diversification strategies where beef investments are included in a portfolio of investments including non-agricultural assets.

B. INVESTMENT STRATEGIES

Table 3 provides a comparison of the results of the various investment strategies that were considered.

	MEAN RLZED RET. (%)	MSE	ROOT MSE (%)	BETA B	CORR. COEFF $r_{(x,y)}$	SYS. RISK (%)	NON SYS. RISK (%)
STRAT. 1	6.32	1690.2	41.1	0.64	0.59	24.2	16.9
STRAT. 2	9.00	1170.3	34.2	0.40	0.44	15.1	19.1
STRAT. 3	13.48	1951.4	44.2	0.66	0.56	24.8	19.4
PORTFOLIO	4.65	1417.1	37.6	1.00	1.00	37.6	0.0
T-BILLS	1.41	0.0	0.0	0.0	-	-	-

Strategy 1 assumes that investments are made in beef feeder cattle for every month over the 13 years.

FIGURE 1
REALIZED NET RETURNS

FIGURE 2
REALIZED NET RETURNS

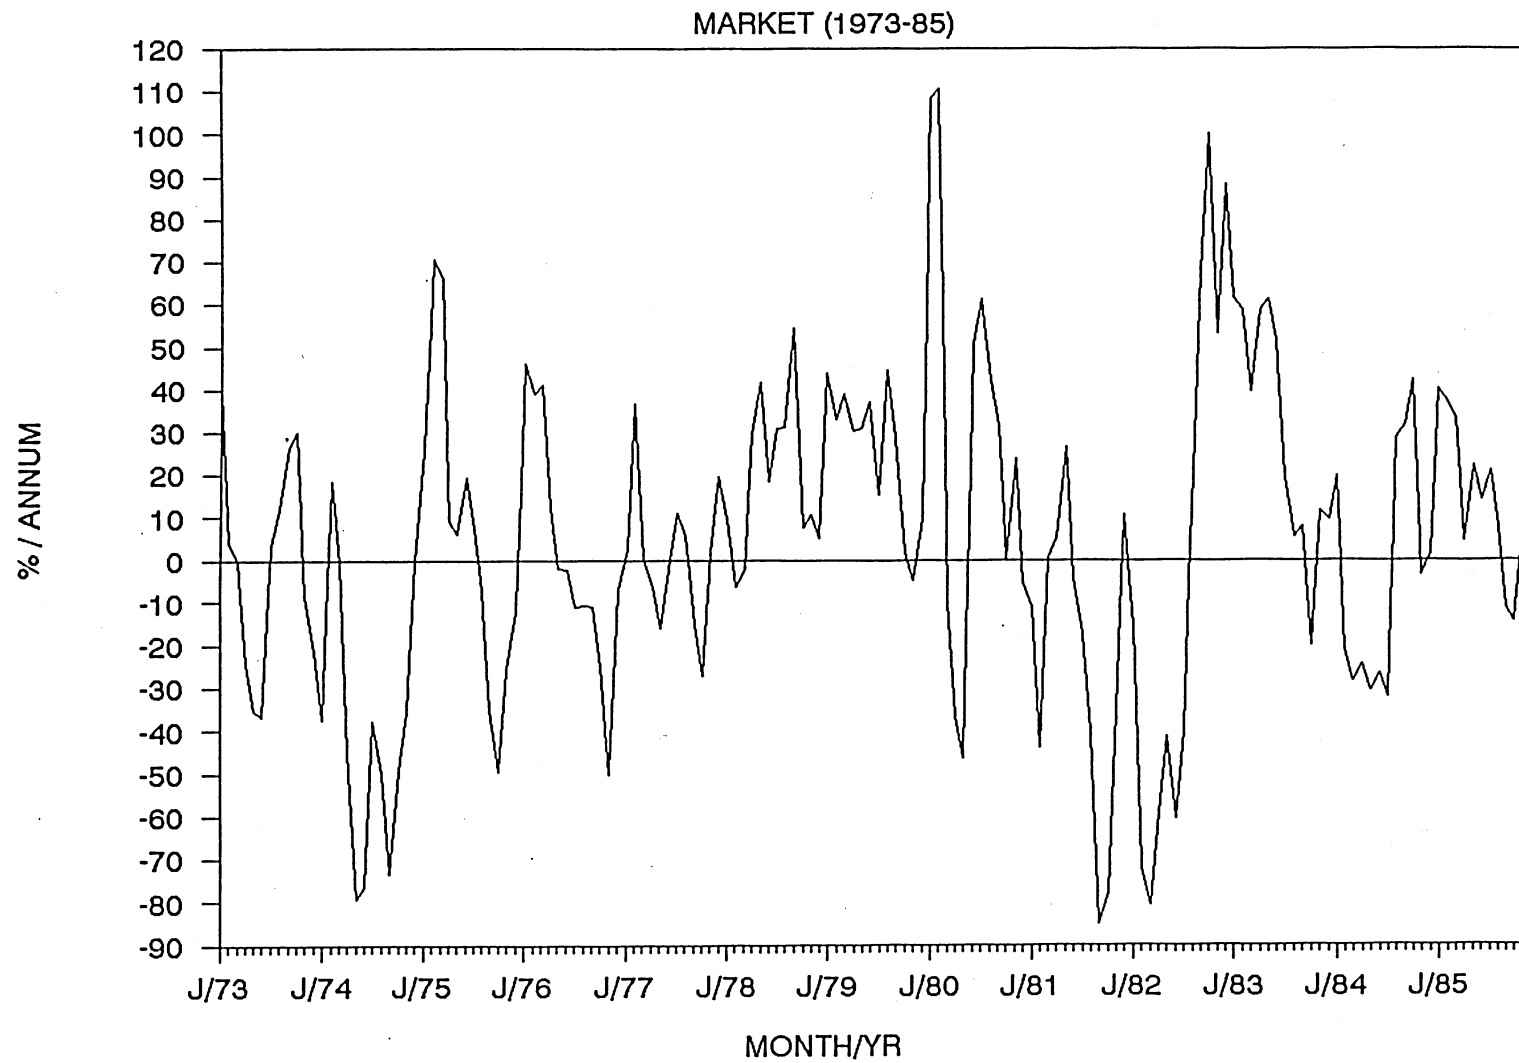

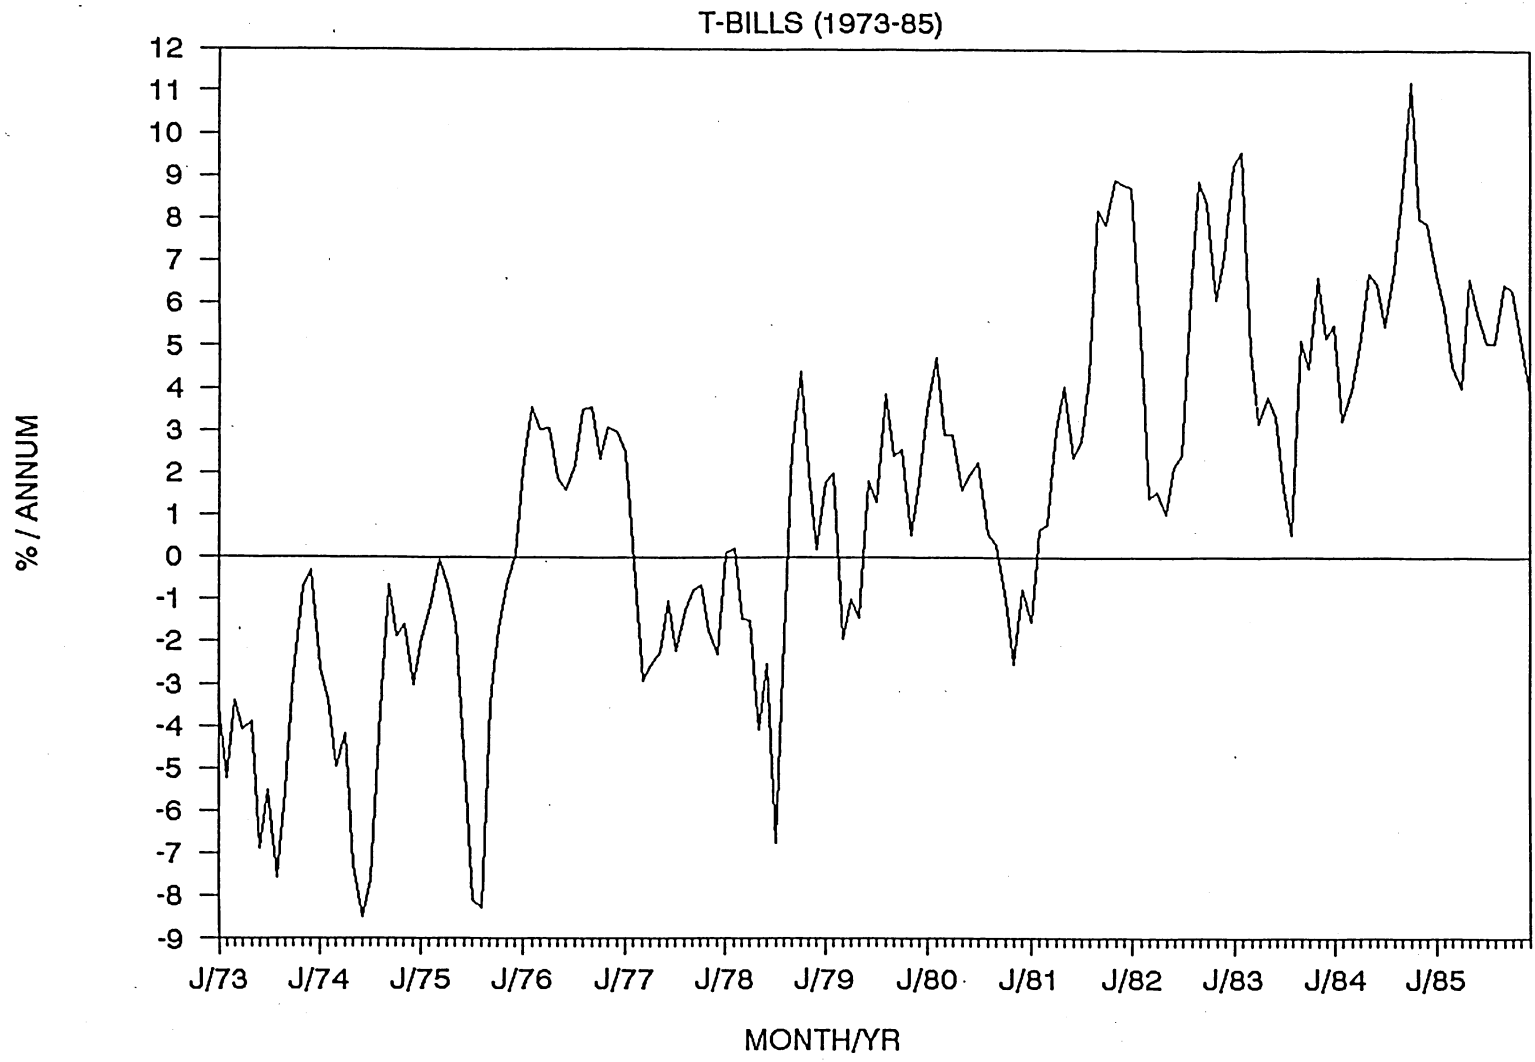

FIGURE 3

REALIZED NET RETURNS

Strategy 2 assumes that the investor is more selective and that the decision to invest in the feedlot is based on the predicted nominal returns on the beef investment being greater than the nominal returns to a 90 day T-bill. When anticipated returns for the T-bills are greater than for the beef cattle the investment will be in the T-bills.

Strategy 3 uses the same decision process for selecting investments as strategy 2 except that the return and risk measurements are based only on the periods in which beef investments were made. For instance, if 100 out of the 156 time periods had predicted beef returns higher than T-bill returns for that period then these 100 time periods would be used to calculate mean returns and risk levels. The intent of this strategy is to isolate the returns and risk for the beef investment under conditions where the decision to invest is constrained by having predicted returns higher than T-bill returns.

The fourth alternative is the market portfolio which was described earlier as being represented by the TSE 300 Total Returns Index.

The fifth alternative is to invest in a riskless asset. In this case the riskless asset is represented by 90 day Treasury Bills.

Strategy 2 had a mean real annual return of 9.00% and a root MSE of 34.2%. The higher returns from strategy 1 were due to the replacement of most high negative beef returns with T-bill returns. The risk level was also lower because the T-bills are a riskless asset. This indicates that strategy 2 is superior to strategy 1 because of higher returns and lower risk.

The beta value for strategy 2 is 0.40 which is lower than for strategy 1. This indicates that strategy 2 would contribute less risk to a portfolio than strategy 1. It is also much lower than the beta for the diversified portfolio which is 1.0. This investment strategy, when added to the portfolio, would lead to higher returns and lower levels of risk for the portfolio.

Strategy 3 provides mean real annual returns of 13.48% and a root MSE of 44.2%. The higher returns as compared to strategy 1 are due to most of the large negative returns being eliminated by the selective process. While returns do increase significantly, the overall risk level only increases slightly. This would indicate that the investor could increase average returns in beef feedlot investments and still not increase risk levels by being selective and only choosing to invest when returns exceed those offered by riskless investments.

The beta value for strategy 3 is 0.66. While the beta is not significantly different from strategy 1 the higher level of returns means that adding this investment to the portfolio (keeping in mind that this investment is only made during certain periods) will mean that the beta of the portfolio is decreased and average returns are increased. The levels of systematic and nonsystematic risk for this alternative were virtually the same as for strategy 1.

The T-bill investment has a mean real annual return of 1.41%. While it has considerably lower return than any of the other investments it also has no risk. It will have a beta of 0 because it is a riskless investment and therefore market risk movements do not affect it. Based on this it would be a good investment to add to the portfolio in terms of reducing risk but due to its low average return, the average returns of the portfolio would decrease as well.

C. SOURCES OF RISK

As outlined in the methodology section, there are several differences in the predictive model from the realized model. Four of these differences involve variance in production parameters while the other one is slaughter price. In order to isolate the portion of MSE contributed by the four production variables their mean values were placed into the realized returns model and the MSE was measured again in order to see how much reduction in MSE occurred. The magnitude of the reduction in MSE would indicate what portion of risk is attributable to these factors. The resulting MSE is virtually unchanged which means that the only source of variation between realized and

predicted returns is the variation between realized and predicted slaughter price. The risk due to production variables is so small it does not affect total MSE. In this case the variation in slaughter price is the difference between the realized price and the futures contract price.

MSE can be separated into components to reflect the effects of revenue, costs, and the covariance between these two variables.²⁵ The equation to measure total MSE is as follows:

$$TOTAL\ MSE = MSE_{(rev)} - 2COV_{(rev, cost)} + MSE_{(cost)} \quad (43)$$

$$TOTAL\ MSE = MSE_{(rev)} - 2COR_{(rev, cost)} \cdot RMSE_{(rev)} \cdot RMSE_{(cost)} + MSE_{(cost)} \quad (43.1)$$

Table 4 lists the components of MSE and the proportions of the total which each one exhibits. They are listed in real dollars as opposed to percentages.

	MSE	ROOT MSE
REVENUE	116,756,328	10,805
2*COV _(rev, cost)	1,717,212	-
COST	875,347	936
TOTAL	115,914,462	10,766

As can be seen from Table 4 almost all risk is due to variation in revenue with the other components being insignificant. These numbers further the conclusion that virtually all of the risk involved in investing in beef feeder cattle is due to slaughter price changes and not changes in production variables which would affect costs.

D. TESTS FOR TRENDS OVER TIME AND AUTOCORRELATION

Several tests were conducted to determine, first of all, if there was a trend over time in the level of returns or level of risk that were measured and secondly, if autocorrelation exists with realized net returns or with risk. The results are shown in Table 5. All tests assume a 5% confidence level.

	T-STAT	T-STAT CRIT. VALUE	R ²	DURBIN H-STAT	D.F.
TREND - RET.	-0.457	1.96	0.0014	-	154
TREND - ERROR	-2.934	1.96	0.0529	-	154
A.C. - RET.	13.341	1.96	0.5377	4.72	153
A.C. - ERROR	6.939	1.96	0.2390	2.36	153

The first test was to regress realized net returns against time. The resulting t-statistic was calculated to be -0.457 which is below the critical value of 1.96 and thus indicates that time was not significant in affecting the level of net returns and that no trend is apparent in the data over the time period studied.

²⁵ Refer to Appendix C for a mathematical description of the components of variation in this model.

The second test was to regress errors in predicting net returns against time. The resulting t-statistic of -2.934 indicates that time was significant in affecting returns and that during the time period studied there was some type of trend occurring in the data.

Tests were also conducted to detect the existence of autocorrelation in net returns and in the error term. The statistic used for these tests is the Durbin-h statistic and is calculated using the following formulas:

$$h = \hat{\rho} \sqrt{\frac{n}{1 - n \cdot (VAR\beta_1)}} \quad (44)$$

$$\hat{\rho} = 1 - 0.5d \quad (45)$$

where; n is the number of observations

$\hat{\rho}$ is the rho value for the Durbin-Watson statistic

d is the Durbin-Watson statistic

$VAR\beta_1$ is the sampling variance in the coefficient of the independent variable in the regression.²⁶

The test for autocorrelation in the realized net returns series resulted in an h-statistic of 4.72 which indicates the existence of autocorrelation at the 95% confidence level.²⁷

The test for autocorrelation in the series of error terms between realized and predicted returns resulted in an h-statistic of 2.36 which indicates the existence of autocorrelation at the 95% confidence level.²⁸

²⁶ For further discussion on the use of the Durbin-h statistic consult Johnston (1984) or Johnson, Johnson, and Buse (1987).

²⁷ The actual calculation of the h-statistic for this test is as follows;

$$\hat{\rho} = 1 - 0.5(1.4531) = 0.27345$$

$$h = 0.27345 \sqrt{\frac{155}{1 - 155(0.0031)}}$$

$$h = 0.27345 \sqrt{298.36} = 4.72$$

²⁸ The actual calculation of the h-statistic for this test is as follows;

$$\hat{\rho} = 1 - 0.5(1.8155) = 0.09$$

$$h = 0.09 \sqrt{\frac{155}{1 - 155(0.005)}}$$

$$h = 0.09 \sqrt{688.89} = 2.36$$

V. CONCLUSIONS

The results of this study have shown that:

1. Continuous investment in heavy beef feeder steers over the period from January, 1973 to December, 1985 yielded average real annual returns of 6.32% with a root MSE of 41.1%.
2. The beta value of the beef investment is 0.64. This indicates that if it was incorporated into a market portfolio the overall beta of the portfolio would be decreased and average returns would be increased, thus making it a potentially attractive investment alternative.
3. The proportion of nonsystematic risk in the beef investment is relatively high, thus indicating that a large portion of the risk can be diversified away.
4. When a strategy is considered whereby predicted nominal beef returns are compared to predicted nominal T-bill returns the average real annual returns rise to 9.0% and the RMSE decreases to 34.2%.
5. A third strategy of selective investment in this enterprise whereby investment is only undertaken when predicted nominal returns exceeded the nominal returns on treasury bills results in a much higher average rate of return (13.48%) with no change in the level of risk.
6. Almost all of the risk in this investment can be attributed to errors in predicting slaughter price. Production variables had a negligible effect on risk.
7. Tests for time trends and autocorrelation indicate that there is a trend in the prediction errors of net returns for beef and autocorrelation in the realized returns. Neither of these issues were investigated in greater detail.

In the course of conducting this research several areas which necessitate further study have become apparent.

Death loss is a harsh reality for feedlot operations and potentially a source of high risk, depending on the capabilities of the feedlot manager. Unfortunately, there is no sound data available on the aspect of death loss and morbidity rates for feedlots that could be used in this study to measure its effects. Research to develop this data is necessary in order to refine risk estimates for beef feedlots.

In certain instances assumptions were made as to covariance relationships between variables in the model. Although in most cases these assumptions can be adequately explained there are cases where this approach was necessitated through lack of data. An example of this would be the relationship between localized feed restrictions and the price of feed.

No attempt was made to consider the consequences of Tripartite Stabilization on risk levels as it was not in effect during the time period being covered by this study. A further study of the risk and returns to a similar investment under Tripartite Stabilization is necessary to determine the effects of this program.

Further analysis of autocorrelation or trends which occur in the data might be beneficial in improving the accuracy of predicting beef investment returns.

Accurate investment decisions require information that reflect as closely as possible current conditions. It is therefore necessary that the database developed for this study be continually updated to ensure that risk and return estimates reflect the most recent information available.

The purpose of this study has been to develop a better understanding of the sources of risk facing an investor in beef feeder cattle, to measure the returns and risk associated with this enterprise, and to examine how this investment alternative may fit into an investor's portfolio. While it has limitations which must be recognized and considered, it nonetheless serves to develop a base of information and ideas from which the understanding and study of risk as it pertains to beef production can be improved.

APPENDIX A - BASIS PREDICTION

The first step in predicting basis values for each time period was to calculate the real basis by subtracting realized prices from futures prices for each time period and converting them to real dollars using a CPI. The next step was to account for any trends that may have occurred in the real basis over time.

If it was assumed that there was no trend over time then the predicted basis values for each period could be found by calculating the average real basis and converting it to nominal dollars for each respective time period. Figure 4 shows that when average annual basis values were plotted there appeared to be an upward trend over time. In order to determine the significance of this trend the real basis values were regressed against time periods.

The regression equation to predict basis values is as follows:

$$\hat{y} = \alpha + \beta(x)$$

where: \hat{y} is the dependent variable (predicted basis)

α is the constant term

β is the coefficient of the independent variable and measures the slope of the dependent variable

x is the independent variable (time period).

The regression determined the following values for the coefficients:

$$\alpha = -0.053$$

$$\beta = 0.001425$$

$$st. \text{ err. of } \beta = 0.000387$$

The null and alternative hypothesis for this test is as follows:

$$H_0: \beta = 0$$

$$H_a: \beta \neq 0$$

A t test value is calculated where:

$$t = \frac{\beta}{st. \text{ err. } (\beta)}$$

$$t = \frac{0.001425}{0.000387} = 3.68$$

The critical t value at a 5% confidence level is 1.96 which indicates that the null hypothesis is rejected and there is a significant trend.

In order to incorporate this trend the regression equation outlined above is used to predict real basis values for each period which are then converted to nominal values using a CPI.

The second consideration in predicting basis is the existence of seasonality in the data. Figure 5 indicates the average monthly basis over this 13 year period. It would initially appear that there is a lot of seasonality in the data due to large fluctuations between months. However, when a t test is done it was found that due to the large standard deviation within months this seasonal variation was not significant from a predictive point of view because all calculated t values are inside the critical range. Therefore, seasonality was not considered when predicting basis values. Table 9 lists the data used in determining the significance of seasonality.

APPENDIX B - STANDARD ERROR RISK MEASUREMENT

One question which arose from the research would be the effect on risk of spreading feedlot investments out over a number of feedlots in order to minimize the risk associated with management practices. In order to measure the effects of this strategy standard deviation measurements for several variables were replaced by standard error measurements. Standard error is measured using the following formula:

$$S.E. = \frac{S.D.}{\sqrt{n}}$$

where; *S.E.* represents standard error
S.D. represents standard deviation
n is the number of observations.

The S.E. was then used in the simulation procedure in place of S.D. to measure the variance in three variables; feed conversion, average daily gain, and treatment costs.

The simulation with feed conversion was conducted using S.E. in order to reduce variance in feed requirements. Average daily gain was altered in order to reduce variance in yardage costs and treatment costs were altered to see if the variance could be reduced there as well.

The results are shown below in Table 7. There is practically no change in any of the categories from when standard deviation was used.

This seems to concur with results found when these individual sources of variation were measured and found not to be contributing any variation to the investment. If these variables are not contributing to risk then there would not be any benefit to spreading the investment around to different feedlots in order to reduce risk. The main source of risk is slaughter prices and this is assumed to be the same for all feedlots.

If death loss variations were included in the model it might be possible that diversification of an investment among feedlots might be beneficial but this theory was not testable with this model.

TABLE 7 : BEEF INVESTMENT RISK AND RETURN USING STANDARD ERROR.			
MEAN RET.	MSE	ROOT MSE	BETA
6.60	1716	41.4	0.64

APPENDIX C - MSE COMPONENTS

The MSE can be broken down into its components in the following manner ;

$$MSE = \frac{\left(\sum_{i=1}^n [(P_i Y - \hat{P}_i Y) - (C_i - \hat{C}_i)]^2 \right)}{n-1}$$

$$MSE = \frac{\left(\sum_{i=1}^n [Y(P_i - \hat{P}_i) - (C_i - \hat{C}_i)]^2 \right)}{n-1}$$

$$MSE = \frac{\left(\sum_{i=1}^n [Y^2(P_i - \hat{P}_i)^2 - 2Y(P_i - \hat{P}_i)(C_i - \hat{C}_i) + (C_i - \hat{C}_i)^2] \right)}{n-1}$$

$$MSE = Y^2 \sum_{i=1}^n \frac{(P_i - \hat{P}_i)^2}{n-1} - 2Y \sum_{i=1}^n \frac{[(P_i - \hat{P}_i)(C_i - \hat{C}_i)]}{n-1} + \sum_{i=1}^n \frac{(C_i - \hat{C}_i)^2}{n-1}$$

$$MSE = Y^2 VAR_{(p)} - 2Y COV_{(p,c)} + VAR_{(c)}$$

$$MSE = VAR_{(rev)} - 2Y COV_{(p,c)} + VAR_{(c)}$$

where; MSE is the mean square error

Y is the total kg of beef for sale and is constant

P_i is the observed price of beef per kg

\hat{P}_i is the predicted price of beef per kg

C_i is the observed total cost of producing beef per lot

\hat{C}_i is the predicted cost of producing beef per lot

n is the number of observations

i is the time period.

APPENDIX H - REALIZED REVENUE

NO. OF ANIMALS PURCHASED :	100
DEATH LOSS (% OF ANIMALS) :	0.4
NET SALES (# OF ANIMALS) :	99.6
SALE WEIGHT (KG) :	520
SHRINK PERCENTAGE :	4
NO. OF LOTS USED TO MEASURE GRADE	
DISCOUNT :	117
WTED REAL MEAN DISCOUNT (\$/CWT) :	0.16
WTED REAL MEAN DISCOUNT (\$/KG) :	0.0035

This table provides a time series of realized returns on the beef feedlot investment based on a set market weight of 520 kg and a shrink of four percent. The price series is based on direct to packer sales which is calculated as a proportion of auction market sales due to lack of data on direct to packer sales for this time period. There is a simulated variance of grade discounts included in the model.

APPENDIX I - REALIZED STEER COSTS

PURCHASE WEIGHT OF STEERS (KG) :	380
NO. OF STEERS PURCHASED :	100

This table lists the time series of realized steer costs based on a constant purchase weight of 100 steers at 380 kg. The price series used is the Edmonton Stockyard prices for good steers.

MM/YR	PURCHASE WT (KG)	PRICE (\$/CWT)	PRICE (\$/KG)	STEER COST (\$)
Oct-72	380	38.99	0.8578	32,596

APPENDIX J - REALIZED FEED COSTS

NO. OF ANIMALS PURCHASED :	100
DEATH LOSS (% OF ANIMALS) :	0.4
% OF FEED CONSUMED BY THE ANIMALS THAT DIE :	25
NO. OF ANIMALS FED :	99.7
FEED CONVERSION -- MEAN (KG) :	7.102
-- S.D. (KG) :	0.33
-- VAR. (KG) :	0.1089
TOTAL GAIN PER ANIMAL (KG) :	140
TOTAL FEED REQ. -- MEAN (KG/LOT) :	99,130
--- S.D. (KG) :	4,606
--- VAR. (KG) :	21,216,526
FACTOR TRANSFORMING BARLEY PRICE TO TOTAL FEED PRICE :	1.082
BARLEY FREIGHT - 1988 (\$/T) :	6.50
FEED PROCESSING - 1984 (\$/T) :	11.05
% OF F.I.P.I. USED TO ADJUST BARLEY FREIGHT ---- FUEL :	33
---- M.V. MAIN. :	67

This table provides a time series of feed costs using a barley based ration with a time series of prices based on barley prices. Feed consumption is based on industry estimates with a simulated variance included.

MM/YR	RLZED TOTAL FEED REQ. (KG)	BARL. (\$/T)	FEED TRNS \$/T	FEED COST \$/T	TOT. INI. FEED COST \$/LOT	FEED ADJ. \$/LOT	FEED PRO. COST \$/T	FEED PRO. COST \$/LOT	TOT. FEED COST \$/LOT

APPENDIX K - REALIZED YARDAGE COSTS

O --- STRAW USED (KG/HEAD/DAY) :	0.91
D --- AVERAGE DAILY GAIN -- MEAN (KG/DAY) :	1.48
--- VAR. (KG/DAY) :	0.036
E --- NO. OF ANIMALS FED :	99.7
INDEX PROPORTION FOR YARDAGE ---- SUPPLIES & SERVICES :	100
INDEX PROPORTIO FOR BEDDING --- LEGUME AND GRASS :	100
TOTAL GAIN (KG) :	140
YARDAGE COST AS OF JULY, 1987 (\$/HEAD/DAY) :	0.15
BEDDING COST AS OF JULY, 1987 (\$/HEAD/DAY) :	0.04

This table provides a time series of yardage costs based on daily yardage costs and bedding costs. A simulation of ADG variance is included which allows for variance in the days on feed.

APPENDIX L - REALIZED TREATMENT COSTS

Zo --- NO. OF ANIMALS TREATED :	100
I.T.P. PREMIUM RATE (%) :	1

This table provides a time series of realized treatment costs based on treatment costs per animal and an ITP premium. The treatment cost per animal includes a simulated variance.

APPENDIX R - PREDICTED REVENUE

NO. OF ANIMALS PURCHASED :	100
DEATH LOSS (% OF ANIMALS) :	0.4
NET SALES (# OF ANIMALS) :	99.6
SALE WEIGHT (KG) :	520
SHRINK PERCENTAGE :	4
NUMBER OF LOTS USED TO MEASURE GRADE DISCOUNT :	117
WTED REAL MEAN DISCOUNT (\$/CWT) :	0.16
WTED REAL MEAN DISCOUNT (\$/KG) :	0.0035

This table provides a time series of predicted revenue based on the use of Chicago futures prices at the time of purchase to predict sale price.

MM/YR	MARKET WT (KG)	PRICE (\$/KG)	WEIGHTED DISCOUNT (\$/KG)	PRICE LESS MEAN DISC (\$/KG)	REVENUE (\$/LOT)

APPENDIX S - PREDICTED STEER COSTS

PURCHASE WT OF STEERS (KG/HEAD) :	380
NO. OF STEERS PURCHASED :	100

This table provides a time series of predicted steer costs. These costs are the same as for realized steer costs since steer costs are assumed to be known at the beginning of the period.

MM/YR	PURCHASE WT. (KG)	PRICE \$/CWT	PRICE \$/KG	STEER COST (\$)

APPENDIX T - PREDICTED FEED COSTS

NO. OF ANIMALS PURCHASED :	100
DEATH LOSS (% OF ANIMALS) :	0.4
% OF FEED CONSUMED BY THE NO OF ANIMALS THAT DIE :	25
NO. OF ANIMALS FED :	99.7
FEED CONVERSION --- MEAN (KG) :	7.102
S.D. (KG) :	0.33
VAR. (KG) :	0.1089
TOTAL GAIN PER ANIMAL (KG) :	140
TOTAL FEED REQ. (KG/LOT) :	99,130
S.D. IN FEED REQ. (KG/LOT) :	4,606
VAR. IN FEED REQ. (KG/LOT) :	21,216,525
FACTOR TRANSFORMING BARLEY PRICE TO TOTAL FEED PRICE :	1.082
BARLEY FREIGHT - 1988 (\$/T) :	6.50
FEED PROCESSING - 1984 (\$/T) :	11.05
% OF F.I.P.I. USED TO ADJUST BARLEY FREIGHT PRICE --- FUEL :	33
--- M.V. MAIN. :	67

This table provides a time series of predicted feed costs based on a mean level of feed consumption of a barley based ration. Feed prices are based on barley prices at the beginning of the feeding period.
