EXPLAINING PARTICIPATION IN THE COLORADO REPUBLICAN RIVER AND
NEBRASKA PLATTE-REPUBLICAN RESOURCES AREA CONSERVATION RESERVE
ENHANCEMENT PROGRAMS

Abstract

Agricultural land retirement is increasingly used to conserve groundwater resources, reduce challenges associated with the conjunctive use of water resources, and meet streamflow compliance. This study explores the factors that influence the participation of agricultural producers in the Colorado Republican River and Nebraska Platte-Republican Resources Areas Conservation Reserve Enhancement Program (CREP). A better understanding of what leads agricultural producers to enroll in CREP could be used to inform program managers on how changing the incentives offered or expanding eligible area would impact enrollment and ultimately groundwater conservation. We develop a theoretical model of CREP participation using a random utility framework that contains the incentives offered for participation, opportunity costs of participation, and aquifer and soil characteristics. We then construct a dataset of participating wells and eligible non-participating wells and generate spatial measures of the explanatory variables. We empirically investigate participation using Probit models, which are estimated with data from the three basins aggregated and also each basin separately. The sign on many of our estimated significant coefficients varies across the three models. For the Colorado and Nebraska Republican models, we find that an increase in saturated thickness decreases the probability of participating in CREP.

Introduction

Groundwater rights have been overappropriated in several basins of the Great Plains. This has depleted rivers and creeks to the extent that some states have experienced difficulty complying with interstate streamflow compacts. The USDA, states, and local water conservation districts have used agricultural land retirement programs to conserve groundwater resources, reduce challenges with the conjunctive use of water resources, and meet streamflow compliance.

One such agricultural land retirement program is the Conservation Reserve Enhancement Program (CREP). CREP pays farmers to convert land to a conservation practice and temporarily or permanently restricts producers from irrigating. Significant financial resources are currently devoted to retire agricultural land and reduce water use through Conservation Reserve Enhancement Programs in Colorado, Nebraska, Kansas, and Idaho.¹

This paper explores the factors that influence agricultural producers to participate in the Colorado Republican River and Nebraska Platte-Republican Resources Area Conservation Reserve Programs. Many economic studies have explained landowners' enrollment decisions in the Conservation Reserve Program or similar land retirement programs. Kingsbury and Boggess (1999), Armstrong et al. (2011), and Yeboah, Lupi, and Kaplowitz (2015) use survey methods to assess the determinants of hypothetical participation in conservation programs. Lynch and Brown (2000) use an optimization model to simulate an agricultural producer's decision to enroll land in the Maryland Chesapeake Bay CREP. Konyar and Osborn (1990), Cooper and Keim (1996), Parks and Schorr (1997), Plantinga, Alig, and Cheng (2001), and Suter, Poe, and Bills (2008) use county-level data to estimate limited dependent variable models of enrollment in land retirement programs. To our knowledge, this is first study to incorporate microdata in participation models and the first to model the participation of landowners in a land retirement program with the objective of reducing water consumption. A better understanding of what leads producers to participate will be useful for predicting how changing the incentives or expanding the eligible area will impact enrollment.

¹ Conservation Reserve Enhancement Programs have been implemented with different objectives throughout the United States. CREPs in the Northeast and Midwest are generally aimed at reducing runoff into streams while CREPs in the Great Plains and Mountain region have the goal of reducing water use. The general objective of CREPs in California and the Northwest is to improve wildlife habitat.

This paper begins with a summary of the Colorado and Nebraska Conservation Reserve Enhancement Programs and a review of economic studies of participation in land retirement programs. Next, we develop a theoretical model of participation, describe the model we estimate and the variables used in the model, and detail how the variables in the study were generated. Finally, we present and discuss our results and conclude by noting some of the limitations of our study and potential areas for further research.

Summary of Colorado and Nebraska Conservation Reserve Enhancement Programs

The Nebraska Platte-Republican Resources Area and Colorado Republican River Conservation Reserve Enhancement Programs are state-federal cooperative programs that remove land from agricultural production to improve environmental conditions and reduce ground and surface water use. The Nebraska Platte-Republican CREP was implemented in 2005 and the Colorado Republican CREP was implemented in 2006. This section will discuss the relationship between CREP and the Conservation Reserve Program, the area and land eligible for enrollment in the Colorado Republican and Nebraska Platte-Republican Conservation Reserve Enhancement Programs, the conservation practices that are adopted, and the incentives offered to producers for participation in these programs.

Relationship to the Conservation Reserve Program

The Conservation Reserve Enhancement Program is a subsidiary program to the larger Conservation Reserve Program (CRP). The CRP is the primary program in the United States that removes land from agricultural production. The CRP was established in 1985 and has grown to enroll 24.2 million acres of agricultural land as of August 2015. Approximately 1.6 billion dollars in annual rental payments were made in 2015. The land eligible for enrollment,

conservation practices established by participants, and the payment incentives offered in the CREP are very similar to those in the CRP. The individual Conservation Reserve Enhancement Programs generally target more specific areas and conservation issues than the CRP. The CREPs are partnerships between the USDA and state or local organization involved whereas the Conservation Reserve Program is solely administered by the USDA.

Eligibility for Enrollment

The land eligible for enrollment in both the Nebraska and Colorado CREPs must be located within specified areas and meet prior irrigation criteria. Administrators of the Colorado Republican CREP have an objective of enrolling 35,000 acres of cropland throughout the Republican River Water Conservation District (RRWCD). This includes all or portions of Kit Carson, Logan, Phillips, Sedgwick, Washington, and Yuma counties. Figure 1 displays the area eligible for the Colorado Republican CREP. The area eligible to enroll in the Nebraska Platte-Republican Program includes land within 2.5 miles of the Republican River and several of its tributaries² and area along the Platte River where surface and groundwater has been designated as over appropriated.³ Figure 2 shows the area eligible for the Nebraska Platte-Republican Resources Area CREP. Land is eligible for enrollment in the Colorado and Nebraska programs if at least six inches of water per acre have been applied in four of the six years prior to enrollment and the land is capable of being planted and irrigated in a “normal manner” (FSA 2005). The Republican program also requires that land be irrigated with at least six inches per acre within

² Including sections of Frenchman Creek, Spring Creek, Stinking Water Creek, Red Willow Creek, Fox Creek, Muddy Creek, Turkey Creek, Spring Creek, Beaver Creek, Driftwood Creek, Buffalo Creek, Rock Creek, Indian Creek, and North Branch Indian Creek with perennial stream flow and all sections of Medicine and Saapa Creeks.

³ Defined as where “pumping a well for 40 years will deplete the North Platte River, South Platte River, Platte River, or base flow tributary by 28 percent of the amount pumped in that time.” Source: State of Nebraska, Department of Natural Resources Order.

the 24 months prior to application. The Platte-Republican CREP allows the enrollment of irrigated land and the corners associated with a center-pivot while the Republican CREP allows only irrigated land to be enrolled.

Conservation Practices

Land enrolled in the program must not be irrigated for the duration of the contract (except for applying six inches per acre in the first year for the establishment of the conservation practice). Participants in the Colorado Republican program are also required to cancel the associated groundwater well permits and abandon the well in perpetuity. Land in both programs must be converted from agricultural production to conservation practices for the duration of the contract (14 to 15 years for the Republican program and 10 to 15 years for the Platte-Republican program). The eligible conservation practices are very similar between the two programs. Both programs allow for the following practices: establishment of permanent native grasses, permanent wildlife habitat, filter strips, and wetland buffers and restoration of wetlands. Establishing rare and declining habitat and wildlife food plots are also included in the Platte-Republican program. Each program contains a specific goal for the number of acres converted for each of the conservation practices. The most frequent conservation practices are the establishment of permanent native grasses and permanent wildlife habitat. These two practices represent 96 percent of the total acreage in the Republican program and 85 percent of acreage in the Platte-Republican program. None of the enrollment caps on conservation practices have been met. After the contract has ended, land in the Nebraska Platte-Republican CREP can be returned to irrigated agricultural production, while land previously enrolled in the Colorado Republican CREP can only return to dryland production because the associated well has been permanently retired.

Incentives for Participation

Eligible landowners are offered annual and one-time payments for participation in the Conservation Reserve Enhancement Program. For the Republican and Platte-Republican CREPs, the largest incentive is the annual rental payment. This payment is based on the irrigated cropland rental rate (and the dryland rental rate if enrolling a dryland corner in the Platte-Republican program) in Nebraska and the irrigated rental rate and distance from river in Colorado. The annual rental payment varies by watershed in the Nebraska Platte-Republican Resources Area CREP and ranges from 110 dollars per acre in the Middle North Platte, Horse Creek, and Pumpkin Creek watersheds to 125 dollars per acre for the Middle Platte and certain watersheds within the Republican Basin. In the Colorado CREP, the annual rental payment is 140 dollars per acre for participants less than one mile from the North or South Fork of the Republican River, 130 dollars per acre for participants greater than or equal to one mile but less than two, 120 per acre for participants greater than or equal two miles but less than four miles, and 115 dollars per acre for participants greater than or equal to four miles. Table 1 displays annual rental payment in the Colorado CREP by distance from North or South Fork of the Republican River. Table 2 shows annual rental payment for each watershed in the Nebraska CREP. Because the annual rental payment varies by distance from the river in the Republican River CREP and by watershed in the Platte-Republican Resources Area CREP, we are able to observe enrollment at different annual rental payments.

In addition, participating land owners are eligible to receive one-time signing incentive payments, practice incentive payments, and cost-sharing for certain conservation practices. Ten dollars per acre for each year of the contract is paid up front for the establishment of filter strips, riparian buffers, and wetland restoration for Platte-Republican Resources Area CREP. Ten to 35

dollars per acre, depending on distance from river, is paid for participating in the Republican CREP. There are also practice incentive payments offered to participants. These practice incentive payments are equal to 40 percent of the total eligible costs for installing filter strips and riparian buffers and restoring wetlands in Platte-Republican CREP and 40 percent of total eligible costs for installing riparian buffers in Republican CREP.⁴ Fifty percent of eligible reimbursable costs are covered for all conservation practices in the Platte-Republican CREP. In the Republican CREP, 50 percent of eligible reimbursable costs for establishing riparian buffers are covered and 55 to 80 percent of eligible reimbursable costs are covered (depending on distance from river) for all other conservation practices. In the Republican CREP, enrollees are also paid 33 to 133 dollars in the 5th, 10th, and 15th years.⁵ Table 3 summarizes the incentive payments offered for enrollment in the Republican and Platte-Republican CREPs.

Literature Review

Previous economic studies of participation in agricultural land conservation programs employ surveys of hypothetical participation, simulations of a landowner's choices, and county-level enrollment data to determine the factors that influence participation. The following section reviews articles that attempt to explain participation in conservation programs—focusing on methods and variables used in each study and highlighting the advantages and shortcomings of each.

Surveys of hypothetical participation ask a respondent if he or she would enroll land in a given conservation program over a specific period for a specified annual payment. These surveys

⁴ This Practice Incentive Payment is included in the Republican CREP Fact Sheet but not on the Republican River Water Conservation District website.

⁵ The payments differ based on distance from river.

also gather information on farm and farmer characteristics and, in some cases, environmental and conservation values. Kingsbury and Boggess (1999) use a survey on hypothetical CREP participation in Union and Washington Counties in Oregon. Participation is modeled as a function of annual payment, acres, acreage planted with high value crops, acreage planted with low value crops, and percentage of income from farming, expectations (including planned retirement within ten years and importance of land use flexibility), environmental and program preferences and perceptions, demographic variables, and knowledge or past experience with conservation programs. The coefficient on the incentive payment is positive for Union County, but negative for Washington County. Placing a greater importance on flexibility of land use decreases the probability of enrolling while the availability of cost-sharing incentives increases the likelihood of participating. Perceiving an environmental problem and placing a higher importance on environmental quality is also found to increase participation.

Armstrong et al. (2011) survey agricultural producers in the Cannonsville Watershed Area on current or planned participation in the New York City CREP program. Current or future participation is a function of farmer attributes (education, proportion of known farmers within one mile radius presence of other sources of income, and political ideology), farm characteristics (dairy cattle on farm, crop acres, and pasture acres), and farmer attitudes that include resentment towards New York City and attitudes towards the opportunity cost of enrollment. Farmer attitudes towards the opportunity cost of enrolling land and resentment towards water management policies and institutions are found to significantly impact enrollment. In addition, the estimated coefficient on crop acres is positive and significant, implying that landowners with greater acreage are more likely to participate.

Yeboah, Lupi, and Kaplowitz (2015) survey agricultural landowners in the Saginaw River watershed (Michigan) about hypothetical participation in the Conservation Reserve Enhancement Program.⁶ The survey the authors use varies contract length, one-time bonus payments, and cost-sharing incentives in addition to varying the annual incentive payment. Measures of environmental values and attitudes towards filter strips are also included along with the farmer characteristics (age, education, conservation experience, gender, and percentage income from farming). The authors find that higher annual payments and shorter contract lengths increase the probability of enrolling in the program, but one-time signing bonuses and reimbursement for installing filter strips do not have a significant impact on the decision to enroll. Farmer age, experience, and knowledge of conservation programs increase the stated likelihood of enrollment. Positive attitudes and values towards filter strips and protecting the environment also are associated with higher probabilities of participation.

Another technique for determining the factors that affect participation in agricultural land conservation programs is numerical simulation. Lynch and Brown (2000) use an optimization model to simulate a representative⁷ agricultural producer's decision to use land for production, sell for development, or enroll in the Maryland Chesapeake Bay CREP program. The authors then model the optimal acreage to enroll and whether to plant trees or grasses as a riparian buffer. The authors vary crop price, annual rental payment, land price, one time incentive and cost share payments, stumpage prices, and discount rates to determine where enrollment decisions change. At existing crop, stumpage, land prices, and incentive levels, the average farmer enrolls the maximum number of acres in the CREP program (assumed to be ten acres)

⁶ The Saginaw River Valley CREP already exists so the survey samples only landowners who are currently not enrolled.

⁷ The representative farm for the Maryland Chesapeake Bay CREP produces corn on 100 acres.

and the enrolled acreage would be used to plant a forest buffer. As land prices increase because of development pressure, the optimal decision changes from planting a forest buffer and enrolling the land in a contract for 30 years to enrolling land for 15 years in a grass buffer. At high land prices, the optimal decision for the landowner is to not enroll any acreage in CREP. The model used by authors assumes that landowners can renew CREP contracts and that land enrolled in the program does not increase in productivity after remaining idle for 15 years.

Several studies use county-level enrollment data to estimate limited dependent variable models on participation. Konyar and Osborn (1990) model the proportion of acres in a Major Resource Land Area enrolled in the Conservation Reserve Program as a function of the difference in net returns between participation and production returns, land value, percentage of land rented, farm size, average age of producers, and average annual soil loss. All variables included in the model are significant at the five percent level. As net returns to agricultural production decrease or as payment incentives for enrollment increase, the proportion of acres participating in the program increases. If average land value, farm size, and age of farmer increase, participation in the program is expected to decline. Counties with greater percentages of rented farms or greater erosion rates are associated with higher enrollment rates.

Parks and Schorr (1997) model Conservation Reserve Program enrollment for metropolitan and non-metropolitan counties in the Northeast. The proportion of eligible area enrolled in a county is modelled as a function of the maximum allowable rental rate, value of crops, crop production costs, value of land, change in land value between 1982 and 1987, proportion of land designated as of limited agricultural value, proportion of land idle, proportion of farms with annual crop sales less than 10,000 dollars, and proportion of high-value crop sales. The authors reject the hypothesis that the regression coefficients for metropolitan and non-

metropolitan counties are equal by using a Chow Test and run separate regressions for metropolitan and non-metropolitan counties. Counties with a greater maximum allowable rental rate, crop production costs, proportion of low quality agricultural land, and proportion of idle land is associated with greater enrollment rates in non-metropolitan counties. A greater proportion of sales of high-value crops in a county is associated with lower enrollment rates. In non-metropolitan counties, an increase in production costs or an increase in the proportion of low quality land is estimated to increase the proportion of land enrolled. Increases in land values and in the proportion of farms with crop sales under 10,000 dollars decrease county enrollment rates.

Plantinga et al. (2001) estimate supply functions for agricultural conservation land for nine major US regions. For each region, county acres enrolled is modeled as a function of rental payments, eligible land, average land quality, population density, median household income, and dummy variables for states in the region. Regressions are run for each region and each year from 1987 to 1990. For most years and regions, the coefficients on payment, eligible area, and average land capability class are positive and statistically significant. In the North Plains (North Dakota, South Dakota, Nebraska, and Kansas) region, the coefficient on payment is positive but not statistically different from zero and in the Lakes States region (Minnesota, Wisconsin, and Michigan) the coefficient on average land capability class is negative. Agricultural conservation land supply curves are constructed for each region and year and an average of each region for 1987 to 1990. Supply curves for the East Coast region are the most inelastic followed by supply curves for the Lake States, Cornbelt, and South Plains. An increase in CRP payments in the Mountain and North Plains regions are associated with an over proportional increase in agricultural land offered for conservation.

Suter et al. (2008) model CREP enrollment decisions at the county-level as a function of payment incentives, opportunity costs, and county-level factors. The authors begin by highlighting flaws with the incentive variables used in other articles. Using the average incentive payment to enrollees instead of the average offered creates selection bias issues in Konyar and Osborn (1990).⁸ The use of the maximum allowable rental rate to represent the incentive payment in Parks and Schorr (1997) may lead to truncation issues. To obtain unbiased estimates, a payment incentive variable is constructed that is an average of the soil rental rates weighted by the percentage of soil in the area eligible for enrollment. This soil rental rate is then multiplied by the percentage incentive rate to generate the average annual payment offered to the eligible landowners in a given county. The authors also note that estimates of eligible land from the NRCS National Resource Inventory data used in Parks and Schorr are inaccurate, and instead the land eligible for enrollment is determined by adding together buffer areas surrounding streams for each county. The percentage of eligible acres enrolled as riparian buffers in each county is modeled as a function of annual rental payment, one-time payments and cost-share incentives, average farm income, farm size, percentage irrigated cropland, number of cattle per acre, percentage of owner-operated farms, an urban influence index, average property tax, acreage enrolled in CRP, and FSA payroll per farm. The authors use a Tobit method to avoid truncation bias.⁹ The estimated coefficients on annual and one-time payment incentives are positive while the coefficient on urban influence index is negative which indicates that urban development lowers participation and acreage enrolled in the CREP program. Increasing annual and one-time

⁸ Plantinga et al. also suffers from this problem.

⁹ The authors also note that none of the counties included approached the upper limit on maximum enrollment so there was no need to use a doubly censored Tobit model.

payments increases the percentage of eligible land enrolled while an increase in urban influence decreases enrollment rates.

Each method used in the articles detailed above has advantages and shortcomings. Hypothetical participation surveys elicit the environmental perceptions and values and experience with and knowledge of land conservation programs that may affect the participation of a landowner but are not included in studies that use actual enrollment data. As pointed out in Suter et al. (2008), studies using hypothetical surveys often do not predict the acreage enrolled. These surveys also often cover a small geographic area and as a consequence, the findings might not generalize to other areas. Numerical simulation can provide useful insights of a typical farmer's decision to enroll provided that the model accurately represents the actual decision-making. In some cases, understanding the factors that explain enrollment for non-typical producers is of greater interest to policymakers than those that influence a typical farmer. Models using county-level enrollment data do not rely on hypothetical participation but are unable to use detailed information on environmental values and knowledge of conservation programs that may explain participation.

Several themes from the literature are used to guide this study. We avoid issues of using the average payment received by enrollees by using spatially explicit microdata to determine the payment offered at each eligible well. The data also allow us to exclude wells that are not eligible for the program by generating a spatially explicit representation of the area eligible for enrollment. This study is the first of our knowledge to use microdata to model enrollment in CREP. Using microdata will enable more detailed prediction of agricultural producers' participation in CREP which is a useful initial step for policymakers in designing similar

programs. The results from our study will provide program managers a better understanding of how changing incentives or the area eligible will impact enrollment.

Theoretical Model of Enrollment

In this section, we develop a theoretical model of enrollment, describe the variables we use and the model we estimate, and detail how the variables in our model were generated. Let

π_{enroll} be the sum of discounted net returns from enrolling. $\pi_{enroll} = \left(\sum_{t=0}^{14} \frac{1}{(1+r)^t} I_t - \right.$

$\left. (1 - \gamma)R \right) * A$ where I is annual rental payment per acre, γ is the cost share of conservation

practice paid by the USDA, R is the cost of converting an acre to a conservation practice, and A

is the number of acres. Let $\pi_{produce}$ be the sum of discounted net returns from producing an

agricultural good. $\pi_{produce} = \left(\sum_{t=0}^{14} \frac{1}{(1+r)^t} [E(P_t) * E(Y_t) - E(C_t)] \right) * A$ where $E(P_t)$ is the

expected price per unit of production, $E(Y_t)$ is the expected crop yield per acre, and $E(C_t)$

expected cost of production per acre. The expected yield is a function of groundwater availability

(W), soil quality (S), climate conditions (CL), and other inputs (I), $E(Y_t) = h(W, S, CL, I)$. The

expected cost of production per acre is a function of the depth to groundwater (D) and other

inputs (I), $E(C_t) = j(D, I)$. Let $U(\pi_{enroll})$ represent the utility from enrolling in CREP, such that

$V(\pi_{enroll})$ is the observable component of utility from enrolling and ε_{enroll} is the unobservable

component of utility from enrollment, $U(\pi_{enroll}) = V(\pi_{enroll}) + \varepsilon_{enroll}$. Let $U(\pi_{produce})$ be the

utility from production, with $V(\pi_{produce})$ the observable component of utility from production, and

$\varepsilon_{produce}$ be the unobservable component. An eligible producer is expected to enroll acreage if

$U(\pi_{enroll}) > U(\pi_{produce})$. Next, define $\Pr(Enroll)$ as the probability of enrollment, where

$$\Pr(Enroll) = \Pr\left(U(\pi_{enroll}) > U(\pi_{produce})\right)$$

$$\begin{aligned}
&= \Pr(V(\pi_{enroll}) + \varepsilon_{enroll} > V(\pi_{produce}) + \varepsilon_{produce}) \\
&= \Pr(V(\pi_{enroll}) - V(\pi_{produce}) > \varepsilon_{produce} - \varepsilon_{enroll}) \\
&= \Pr(\varepsilon_{produce} - \varepsilon_{enroll} < V(\pi_{enroll}) - V(\pi_{produce})) \\
&= F(V(\pi_{enroll}) - V(\pi_{produce})) \\
&= F\left(\sum_{t=0}^{14} \frac{1}{(1+r)^t} I_t - (1-\gamma)R - \sum_{t=0}^{14} \frac{1}{(1+r)^t} E(P) * E(Y) - E(C)\right)
\end{aligned}$$

If we assume that $\varepsilon_{produce} - \varepsilon_{enroll}$ is distributed normally then $F(\cdot)$ is the cumulative distribution of the normal distribution and we can estimate the probability of enrollment with a probit model.

$\Pr(Enroll) = \Phi(\beta'X)$ where X is the matrix of explanatory variables described above.

Model Estimated

Several variables from the theoretical model above are unobservable or unavailable to be included the econometric model we estimate. The annual rental payment offered for participation is included, but we are unable to determine wells that are eligible for signing incentive or cost-sharing payments. We use distance to nearest stream and a dummy variable if the well is located within 1,895 feet of a stream¹⁰ to identify wells that may be eligible for cost-sharing and signing incentive payments. All else equal, increasing the annual rental payment or being eligible for a signing incentive payment or cost-share are expected to increase the probability of enrollment.

We are also unable to observe all measures of the opportunity cost of land retirement, such as the irrigated rental rate or land sale value, so we include dryland rental rate as a proxy for

¹⁰ 1,895 feet is the diagonal of a quarter-quarter section. We assume if a stream is borders a quarter-quarter section that the land and associated well received a cost-sharing or signing incentive payment.

the irrigated rental rate. We expect that producers with greater dryland rental rates also have higher net returns from production and are less likely to enroll in CREP. We are also able to include irrigated corn yield and several variables that affect the present and future expected yields. Irrigated land capability class is also included as a broad measure of land productivity.¹¹ We expect that wells irrigating poorer quality soil are more likely to be enrolled.

Several measures that affect the volume of groundwater available for current and future production are included such as saturated thickness, specific yield, and hydraulic conductivity. Saturated thickness is the distance from the base to the top of the aquifer, specific yield is the amount of water that drains from a volume of the aquifer, hydraulic conductivity is the volume of water flows through the aquifer within a given time under a gradient. A landowner with higher saturated thickness, specific yield, or hydraulic conductivity has more water available for production, experiences higher yields and net returns from production and is therefore expected to be less likely to participate in the program. Water level change from 1995 to 2005 is also included in the model to represent recent changes in volume available for application.

Landowners who experienced increases in water level might not be as concerned with decreases in water availability and thus might be less likely to retire land as landowners who experienced large decreases in water levels. Hydraulic conductivity, saturated thickness, and initial well capacity also affect the well capacity of producers. Producers with greater initial well capacity are able to apply greater volumes of water, experience greater net returns from production, and are therefore predicted to be less likely to enroll than producers with lower initial well capacity.

¹¹ Irrigated land capability class ranges from one to four with one representing the highest quality land for production.

Available water capacity, saturated conductivity, and percent clay are included to capture the effect of soil quality on expected yields. Available water capacity measures the volume of water held by the soil and made available to plants, saturated conductivity measures the rate at which water moves vertically through saturated soil, and percent clay is the percentage of mineral particles that are clay. We expect that soils containing a greater percentage of clay are better at holding water and nutrients, have greater net returns, and are less likely to be enrolled. We expect that an increase in available water content and saturated conductivity increases the amount of water available to be used by the crop, increases the expected yield, and therefore decreases the probability of enrollment.

Depth to water is included as a measure of the cost of irrigation. Producers with greater depth to the groundwater table face higher costs per unit of irrigation than producers with lower depths to groundwater. These producers therefore experience lower net returns from production, and are predicted to be more likely to enroll in the program. The county-level net irrigation requirement for corn is also included to approximate the amount of irrigation necessary for production in a typical year. It is expected that an increase in the net irrigation requirement increases the cost of irrigation, decreases net returns to production, and increases the probability of participation. We expect that land in areas with a greater median age is more likely to be enrolled because it may be more difficult to sell or rent land in these areas and thus the landowners may choose to retire the land instead of selling or renting. We estimate the probability of enrollment using the observable characteristics described in this section.

Data

The spatial data used in this study are generated from a variety of sources. Retired wells are identified using data provided by the Republican River Water Conservation District and the

Nebraska Department of Natural Resources (DNR). The wells eligible for the Colorado Republican CREP are determined by selecting irrigation wells from a Colorado Division of Water Resources database that are within the Republican River Water Conservation District. Wells eligible for the Nebraska-Platte Republican CREP are determined by subsetting a Nebraska DNR spatial dataset of irrigation wells by the Platte overappropriated area¹² or buffers surrounding the Republican River and eligible tributaries.¹³ The payment incentive offered to producers in the Colorado Republican CREP is generated by calculating the distance from each well to the North or South Fork of the Republican Rivers using the USGS National Hydrography Data for the Republican River. Payment incentives offered in the Nebraska Platte-Republican CREP are created by determining the watershed for each well using USGS Watershed Boundary Data. Irrigated land capability class and irrigated yield is generated using the USDA NRCS Soil Survey Geographic Database (SSURGO).^{14,15} The SSURGO data and soil posting data from the USDA FSA are combined to determine the dryland rental rate in 2005 and 2006. SSURGO data is also used to generate saturated conductivity, available water content, and percent clay. Saturated thickness for 2005, depth to water in 2000, water level change from 1995 to 2005, hydraulic conductivity, and specific yield at each well are generated using USGS Water Resources Spatial Data. County-level median age of operator for 2002 is generated from the USDA NASS Census of Agriculture. Net irrigation requirement at the county-level is generated from data provided by the USDA Risk Management Agency.

¹² Spatial data of the overappropriated area was provided by the Nebraska DNR.

¹³ Using the USGS National Hydrography Data for the Republican River.

¹⁴ We are unable to determine land associated with retired and non-retired eligible wells so we use dryland rental rate, irrigated land capability class, irrigated yield, percent clay, available water capacity, and saturated conductivity of the map soil unit in which the well is located to represent the same variables of the associated land.

¹⁵ A sizable percentage of wells are missing dryland rental rate and irrigated corn yield in Nebraska. Values for these variables were imputed and if missing, the imputed value is used in the regression models.

Table 4 displays CREP enrollment by year for the Colorado Republican, Nebraska Republican, and Nebraska Platte basins. The year of enrollment was determined by the year the well was decommissioned in Nebraska or the year the well permit was cancelled or the well was abandoned in Colorado. We consider enrollments that occurred in 2005, 2006, and 2007 as participants and enrollments that occurred after 2007 as non-participants in our analysis of the Nebraska Platte-Republican CREP. Similarly, we consider enrollments in 2007, 2008, and 2009 as participants and enrollments after 2009 as non-participants in the Colorado Republican CREP. We restrict those counted as participating to the first three years of participation because the annual rental payments did not change over this period. It is also important to note that both CREPs allow the enrollment of surface water, but we have excluded surface water retirements from our analysis.¹⁶

Summary Statistics

Table 5 displays the participation rates for the three regions. Approximately 9 percent of eligible wells participated in the Nebraska Republican basin, 3.62 percent of eligible wells participated in the Colorado Republican region, and 0.63 percent of eligible wells participated in the Nebraska Platte region.

Summary statistics for the explanatory variables for the Colorado Republican, Nebraska Republican, and Nebraska Platte areas are displayed in Tables 6, 7, and 8. The mean annual rental payment offered in the Nebraska Republican basin is slightly greater than in the Colorado Republican and Nebraska Platte basins. Land productivity amongst eligible wells is greater in the Nebraska Platte and Republican basin than the Colorado Republican basin. The average irrigated

¹⁶ Approximately 13 percent of the land retired in the Nebraska Platte-Republican CREP was previously irrigated with surface water.

corn yield and dryland rental rate is much lower for land in the Colorado Republican area than in the Nebraska basins. Average irrigated land capability class is greater in Colorado than in the Nebraska basins. Saturated thickness is greater in the Nebraska Platte region than the other two basins. The mean value of depth to groundwater, average water level change, and net irrigation requirement is greater in the Colorado Republican basin than in the two Nebraska areas. The lower opportunity costs of retirement and saturated thickness in the Colorado Republican basin may lead to a higher participation rate than in the Nebraska Platte basin.

Table 9, 10, and 11 display pairwise correlations between explanatory variables for the Colorado Republican, Nebraska Republican, and Nebraska Platte models. The correlation between annual rental payment and the explanatory variables is much greater in the Nebraska Republican and Platte regions than in the Colorado Republican region. This is because annual rental payment is determined by distance from river in the Colorado Republican, while in the Nebraska regions the irrigated rental rate in the watershed is used to determine the annual rental payment. The irrigated rental rate is probably correlated with many of the explanatory variables. Percent clay and available water content have a very high correlation in the Colorado Republican region. This might signal potential collinearity issues and motivate us to conduct post-estimation collinearity checks on the Colorado Republican model results.

RESULTS

The first column in Table 12 displays estimated coefficients from the model that includes eligible wells in both Colorado and Nebraska.¹⁷ Estimated coefficients on irrigated land capability class and depth to water are positive and statistically significant, while the estimated

¹⁷ Standard errors are clustered at the watershed level.

coefficient on specific yield is negative and statistically significant. The sign on the significant coefficients in this model matches our prior expectations. We expect that increasing irrigated land capability class or depth to water increases the probability of enrollment all else equal and that increasing specific yield would decrease the probability of enrollment. Marginal effects for the variables included in this model are shown in the second column of Table 12. The estimated probability that an eligible well will enroll in CREP in the three regions is 2.2 percent. A decrease in land productivity from irrigated land capability classification II to III (this represents a change from moderately limiting soil that reduces the choice of plants or requires moderate conservation practices to a severely limited soil that reduces the choice of plants or requires special conservation practices or both) increases the probability that an average well is enrolled from 0.022 to 0.028.

A likelihood ratio test is conducted to determine the appropriateness of a pooled model using data from the three regions. The chi-squared statistic for the likelihood ratio test is $LR = -2(LL_{Pooled} - (LL_{CO\ Republican} + LL_{NE\ Republican} + LL_{NE\ Platte})) = -2(-2167.73 - (-375.71 - 1240.15 - 296.67)) = 510.40$. We reject the hypothesis of pooling the data from the three regions based on these values ($P < 0.0001$). Likelihood ratio tests also rejected the pooling the Colorado Republican and Nebraska Republican data, the Nebraska Republican and Platte data, and the Colorado Republican and Nebraska Platte data.¹⁸ Based on the results of these tests, probit regression models are run for each region.

Estimated coefficients from the regression of Colorado eligible wells are displayed in the first column of Table 13. In the Colorado Republican participation model, the coefficient on

¹⁸ The chi-squared test statistic for these hypothesis tests are 213.31, 332.69, and 131.45 respectively. The 95 percent critical value for 19 degrees of freedom is 30.144.

annual rental payment is are positive and statistically significant from zero, while the coefficients on acres, saturated thickness, and well capacity are negative and statistically significant. The sign on these coefficients¹⁹ match our prior expectations. All else equal, increasing the annual rental payment are expected to increase the probability of participation and increasing saturated thickness or well capacity decreases the probability of participation. The first column of Table 14 shows the marginal effects for the variables used in the regression at mean values. The probability that an eligible well is enrolled in the Colorado Republican region is approximately 0.009. The probability that a typical well is enrolled would approximately double if the annual rental payment increased by ten dollars (ten percent increase). An increase of saturated thickness of 10 percent (13 feet) would decrease the probability that a well is enrolled by approximately two-tenths of a percent.

The second column of Table 13 displays the estimated coefficients from the model of eligible wells in the Nebraska Republican region. Estimated coefficients on irrigated yield, saturated thickness, and hydraulic conductivity are negative and statistically significant while coefficients on acres and available water capacity are positive and statistically significant. The sign of the estimated coefficient on available water capacity does not match our prior expectations. Water capacity represents the volume of water held by the soil available for plants. We would expect that an increase in available water capacity would decrease the probability of enrollment all else equal. Marginal effects for the variables used in the regression are displayed in the second column of Table 14. A typical well in the region has an 8.2 percent probability of enrollment. The marginal effect of a one unit increase in available water capacity increases the probability of enrollment by 0.905. However, the value of this variable ranges from 0.048 to

¹⁹ We do not have an expectation on the sign of the acres.

0.220 so a one unit increase in this variable is unrealistic. A more representative increase in available water capacity might be 0.010 which would increase the probability of enrollment for the typical landowner by 0.009.

Estimated coefficients from the model for the Nebraska Platte region are displayed in the third column of Table 13. The estimated coefficient on well capacity is positive and significant while the coefficients on annual rental payment, distance from stream, and net irrigation requirement are negative and significant. Only the sign on distance from stream matches our prior expectations. We expect that increasing annual rental payment and net irrigation requirement would increase the probability of participation all else equal. The third column of Table 10 shows the marginal effects of the variables used in the regression at the mean levels. The probability of enrollment for a typical well is 0.002, which is notably smaller than for the other two regions, and given the small enrollment percentage the changes to the probability of enrollment from unit increases in the variables used in the regression are quite small.

Comparing results across the three regions, none of the estimated coefficients are significant and have the same sign in each region (see Table 14). The estimated coefficient on saturated thickness is negative and significant in the Colorado Republican and Nebraska Republican models. Distance from stream, irrigated yield, available water capacity, and net irrigation requirement are significant in one of the three regression models. The sign on annual rental payment, acres, and well capacity vary between two of the three models.

The sign on estimated coefficients from the Colorado Republican model align better with prior expectations than the Nebraska Republican or Platte models. Table 15 displays the expected sign and estimated sign on the coefficients used in our models. None of the significant coefficients (annual rental payment, saturated thickness, and well capacity) in the Colorado

Republican participation model have signs that conflict with prior expectations (see the first column of Table 13). Four out of the five significant coefficients estimated in the Nebraska Republican participation model are of the expected sign (second column of Table 13). Three out of the four significant coefficients estimated in the Nebraska Platte participation model do not match our prior expectation of sign (third column of Table 13).

Several of the variables used in our model have sizable marginal effects on the probability of enrollment (see Table 14) considering the very small probability that a well is enrolled. If the annual rental payment were to increase by ten dollars in the Colorado Republican region, the probability that a typical well is enrolled is predicted to increase from 0.009 to 0.018. In the Nebraska Republican region, the marginal effect from a 0.01 unit increase in available water capacity increases the probability of enrollment by almost one percent. A ten bushel increase in the irrigated corn yield would decrease the probability of enrollment by 7 tenths of one percent.

Table 16 displays the estimated variance inflation factors from the Colorado Republican CREP participation model. The estimated variance inflation factors of available water capacity and percent clay are greater than 10 which indicates multicollinearity issues with these two variables. As a consequence of this multicollinearity, our standard errors are larger and we are less likely to find statistical significance for these variables than otherwise.

DISCUSSION

This section discusses two important findings from our study and how our results could be used by CREP program administrators. Our estimated coefficient on annual rental payment is positive and matches our prior expectations. This estimate could be used to predict an increase in

enrollment that results from raising the annual rental payment for the Republican CREP. We unexpectedly find that an increase in the annual rental payment has no statistically significant effect on the probability of enrollment in the Nebraska Republican basin and decreases the probability of participation in the Nebraska Platte basin. We are unsure what drives these unexpected results. We may have omitted a variable from our Probit model that affects participation and is correlated with annual rental payment. The permitted allocation for Pumpkin Creek watershed was substantially reduced around when the Nebraska CREP was implemented and this watershed also has a very high participation rate and a low annual rental payment. Unfortunately, we were unable to include groundwater permitted allocations in our Nebraska models. Perhaps adding permitted allocation to our models would change the sign of the estimated coefficient on annual rental payment.

Another important finding is that several of our aquifer, soil, and climactic variables affect the probability of enrollment. Increasing saturated thickness decreases the probability of enrollment in two of our models. Hydraulic conductivity also have a statistically significant impact on enrollment in at least one of the models. Of the soil characteristics, irrigated corn yield and available water content are also statistically significant from zero in one of our three models. Net irrigation requirement affects the probability of enrollment in one of our models. The aquifer, soil, and climate characteristics faced by a producer impact the probability of participation in CREP. These estimates would be very useful to a program manager choosing among potential areas for CREP expansion with the goal of increasing enrollment by the greatest amount.

Limitations

There are several aspects of this study that may limit our findings. We do not observe groundwater pumping prior to or during the enrollment period and are thus unable to determine which wells extracted the required volume of groundwater to be eligible for the program. Wells that used water for irrigation and that were not decommissioned as of 2005 in Nebraska and 2006 in Colorado were considered eligible, non-participating wells. We also cannot associate a groundwater well with the irrigated land so we use the soil characteristics at the well location as those of the land irrigated. If the soil characteristics at the well location and the actual irrigated land differ along another variable, our estimates could be biased. Another limitation is that we are not able to include crop price into our analysis. Price is not included because very few producers enroll after the first three years of the program and we assume producers' expectation of future price does not change from another year of information. Predictions from our model might only apply to years or areas with similar returns to irrigated land as those in Colorado in 2007, 2008, and 2009 and Nebraska in 2005, 2006, and 2007. Another limitation of our study is that there are only four annual rental payment levels in both Colorado and Nebraska and the range of annual rental payments for participation is relatively narrow. The annual rental payments vary from 115 to 140 dollars in Colorado and from 110 to 125 in Nebraska. Few payment levels and a narrow range of payments limit our predictions to small changes in the annual rental payments. The identification in our Nebraska models is less than ideal. Annual rental payment in these areas is based on the irrigated rental rate of the watershed. This is strongly correlated with explanatory variables in our model and might be correlated with our error term. Selection bias issues may arise in our analysis if farmers on poorer quality land are more likely to interact with the Farm Service Agency (FSA), know more about the CREP, and are more likely to enroll as a result of their better understanding of CREP rather than land quality.

Since we do not include a measure of interaction with the FSA in our model, our estimated coefficient on land quality would be biased if this is what actually occurs.

Further Research

There are several areas for further research on the Colorado and Nebraska Conservation Reserve Enhancement Programs. Spatial patterns of well ownership could be incorporated into the model. Well owners near retired wells may experience greater well capacity or lower depth to water than if the well had not been retired. If wells owners are able to internalize this spillover from retirement, they may be more likely to retire wells. Producers in Nebraska and Colorado also may enroll wells and land in the Environmental Quality Incentives Program and the Agricultural Water Enhancement Program. These programs restrict producers from irrigation but allow dryland production. We could construct a model where producers choose to retire land and groundwater, retire groundwater, or retire neither. Estimating potential slippage from the CREP program is also an interesting potential research area. Landowners near retired wells may extract more groundwater or landowners in Nebraska who retired wells may extract more water after the expiration of CREP contract. Understanding if slippage from the CREP occurs would lead to a better understanding of the benefits from retiring wells.
