## MINIMIZING EGYPT'S FOREIGN EXCHANGE DEFICIT FOR 18 CROPS

### INTRODUCTION

In recent years Egypt has experienced huge foreign exchange deficits for the agricultural sector of its economy. Considerable interest exists in changing production patterns as a means of reducing the current gap between the value of imports and exports. Of particular concern in this study is the extent to which production changes are indicated for nine horticultural crops currently in foreign trade. Nine other crops are included to provide a larger basis for obtaining results. A linear programming model is used for determining the optimum production patterns.

Two simplifications are made to limit the scope of the study. Some important farm enterprises, notably the livestock-meat industry, are omitted. Each crop is considered on a national basis without recognizing regional differences. Several additional assumptions, to be mentioned later, are incorporated into the model. It is believed that results are not materially affected.

Shifting from current to optimal land use patterns requires no production of lentils and an expansion of 10 percent for the other eight horticultural crops. It also requires a 5 percent decrease in land planted to wheat, maize, and cotton and an increase of 10 percent in the amount used for rice and the other three nonhorticultural crops. As a consequence, imports are decreased and exports increased, resulting in a substantial reduction in the foreign exchange deficit for these crops. Admittedly, various obstacles, economic and noneconomic, will need to be overcome. The results, however, do indicate the direction in which changes should be attempted to improve the situation.

DATA USED

Nine horticultural products are imported to, or exported from Egypt in significant quantities. These are, in order of planted area: tomatoes, beans, oranges, potatoes, melons, lentils, onions, harricot, and garlic. Nine other crops are included since they compete for the same land. They are wheat, maize, rice, cotton (short and long), sugarcane (type I and type II), peanuts, and sesame.

Conditions prevailing during 1976-1979 are used to define the parameters required for the analysis. Thus 1976-1979 averages are used for yield, production, import, export and domestic consumption of each crop and for the land and water resources available for producing these crops. Other inputs are assumed to be available in adequate amounts from domestic and foreign sources. Average prices during 1976-1979 are used for values of imports, exports and three imported production inputs.

Quantities produced, imported, and exported are converted to equivalent land areas using national average yields. For example, suppose the average yield for cotton produced in Egypt is 0.40 tons per feddan. Then a quantity of 1,000 tons is represented by  $1,000 \div 0.40$ , or 2,500 feddans. Import and export prices are converted similarly to indicate the foreign exchange values per feddan for quantities imported and/or exported.

Estimates for the exchange values for imports of production inputs are limited to three items: fertilizers, insecticides, and machinery. Data for insecticides are included only for cotton and onions. Data for fertilizers and machinery are for imports only, i.e., domestically produced quantities are excluded.

Domestic consumption for each crop is merely set at production minus net exports or plus net imports as the case may be. Water usage is set at average rates experienced during 1976-1979.

It is recognized that substantial shifts in production patterns may change some of the input data. For example, the quantities of imported fertilizer, insecticide and machinery could be altered. Also national yield data might change merely because land with lower yield will tend to be used if production is being expanded or tend to shift to other crops if production is being curtailed.

The input data used for the study are given in Tables A and B at the end of this report.

#### METHODOLOGY

The objective of this linear programming problem is to minimize the sum, in monetary terms, of the net imports of 18 crops and the net imports of three inputs used in their production. This optimization is subject to various constraints imposed on the selection of values for the decision variables.

The first part of the objective function, representing the value of net imports, is expressed by

$$\sum P_j X_j - \sum Q_j Y_j \quad \text{for } j = 1, 2, \dots, 18$$

where  $X_j$  and  $Y_j$  denote, in feddan equivalents, the quantity of crop  $j$  imported and exported, respectively.  $P_j$  and  $Q_j$  denote the value, in Egyptian pounds per feddan, the quantity of crop  $j$  imported and exported, respectively.

The second part, representing the value of the imported production inputs, is expressed by

$$\sum C_j(S_j + W_j) \quad \text{for } j = 1, 2, \dots, 18$$

where  $S_j$  and  $W_j$  denote, in feddan equivalents, the land area used for producing crop  $j$  during the summer and winter seasons, respectively.  $C_j$  denotes the cost per feddan, in Egyptian pounds, of the imports of three inputs (fertilizer, insecticide, and machinery) used in producing crop  $j$ .

Actually the above term gives the cost of three inputs used for the total produced, including amounts consumed domestically. Since domestic consumption for each crop is assumed constant, as noted later, an adjustment is not required.

Hence the objective function is

$$(1) \quad \text{Min } \sum P_j X_j - \sum Q_j Y_j + \sum C_j(S_j + W_j) \quad \text{for } j = 1, 2, \dots, 18.$$

Five sets of constraints are imposed on the selection of the decision variables:  $X_j$ ,  $Y_j$ ,  $S_j$  and  $W_j$ .

This problem is not concerned with the question of whether domestic consumption should be altered for any one of the crops or for their total. In other words, it is assumed that domestic consumption is maintained at 1976-1979 levels. This requires for each crop  $j$ ,  $j = 1, 2, \dots, 18$ :

$$(2) \quad S_j + W_j + X_j - Y_j = K_j$$

where  $K_j$  denotes, in feddan equivalents, the domestic consumption of crop  $j$ . Furthermore, since each  $K_j$  is a constant their sum is a constant which is equal to production plus net imports. Thus,

$$(3) \quad K = \sum K_j = 8.95 \text{ million feddans.}$$

To limit water usage to its 1976-1979 level might unduly restrict changes in production patterns. Hence, the availability of water is set at 28,000 million cu.m., or about 10 percent above the average used in 1976-1979. The water constraint becomes

$$(4) \quad A_j(S_j + W_j) \leq 28,000 \text{ million cu.m.},$$

where  $A_j$  denotes the rate, in cu.m. per feddan, used for crop  $j$ ,  $j = 1, 2, \dots, 18$ .

A total of 4.70 million feddans is assumed available for producing the 18 crops, compared to 1976-1979 plantings on 4.53 million during the summer season and 3.50 million during the winter. Actually no land remains unused. The difference is planted mostly to fodder crops. Introducing the "extra" area insures that production patterns can shift. A larger, or smaller, area could have been selected without affecting the outcome of the optimization.

Table A indicates the season when each crop occupies the land. Five crops use the land throughout the year. For them  $S_j = W_j$ . Five are grown during the summer season only, and five during the winter only. This gives  $W_j = 0$  for the former group and  $S_j = 0$  for the latter. The other three crops and the "fodder" item can be grown either summer or winter and, consequently, no restriction is needed. Symbols  $S_{19}$  and  $W_{19}$  denote summer and winter land, respectively, used for producing "fodder". Summarizing, gives the following constraints on land use:

$$(5) \quad \begin{array}{ll} \sum S_j = \sum W_j = 4.7 \text{ million feddans} & \text{for } j = 1, 2, \dots, 19 \\ \sum S_j = \sum W_j & \text{for } j = 1, 2, \dots, 5 \\ \sum W_j = 0 & \text{for } j = 6, 7, \dots, 10 \\ \sum S_j = 0 & \text{for } j = 11, 12, \dots, 15 \end{array}$$

It is unrealistic to assume a large increase in exports for Egyptian crops, at least for the immediate future. A limitation must be placed on the production of each crop by setting a maximum on the land used or, alternatively, on the amount exported. The latter method is used here. Eleven crops were exported during 1976-1979. Only fragmentary information is available for indicating how much these exports might be expanded. Hence volumes are selected somewhat arbitrarily at approximately 10 percent of 1976-1979 production. These increases appear possible if export sales are sought vigorously. There should be no serious difficulty in expanding production accordingly.

#### SOLUTION

For the 18 crops included in the study the foreign exchange values, in Egyptian pounds, averaged 762 million for imports and 275 million for exports during 1976-1979. Shifting to the optimal solution decreases imports by 69 million and increases exports by 65 million. In addition, a negligible decrease occurs in the value of imported production inputs. The net effect of adopting the optimal land use pattern reduces by 19 percent the foreign trade deficit for these 18 crops.

Changes required to reach optimal levels are summarized in three tables. The first indicates how imports and exports are altered for each crop. At optimum, imports are reduced to zero for beans and type II sugarcane. They are increased by about 8 percent for the other five crops now exported. Imports increase by the amount producible from 161,000 feddans; exports increase by the same amount. Over half of this increase is by the seven horticultural crops now exported. The volume of exports is increased sharply for these crops and for rice.

To implement these shifts in imports and exports necessitates changing land use patterns--see Table 2. Production is zero for lentils at optimum and about 10 percent higher for the other horticultural crops. Two thirds of the decrease in land used for growing wheat, maize and cotton is offset by expanded production of rice and sugarcane. For several crops the shift in production is substantial percentagewise, although not large in terms of the amount of land planted.

Table 3 compares the 1976-1979 foreign exchange position with the optimal situation. The trade deficit declines 19 percent, from 700 million Egyptian pounds to 564 million. The reduction includes a decrease of 69 million in imports, an increase of 65 million in exports, and a slight decrease in the cost of imported production inputs.

The largest change is the decrease of 112 million Egyptian pounds in imports of type II sugarcane. All other imports increase by a total of 43 million. Export values decrease 20.3 million for type I sugarcane and long cotton. They increase 33.0 million for rice, 47.4 million for four horticultural crops (tomatoes, potatoes, melons and orange) and 4.9 million for the other four crops. In other words, for the crops alone (i.e., without the imported production inputs) imports are reduced by 9 percent while exports are increased by 24 percent.

The amount of water needed for the new land use patterns is 4 percent below the volume arbitrarily to be available--see Table 4. On the other hand, the amount needed is 5 percent above that used on the average during 1976-1979. Cotton, maize, rice and sugarcane account for about 80 percent of the total water used in 1976-1979 and also at optimum.

### EVALUATION OF RESULTS

The optimal solution determined here indicates numerous shifts in production and foreign trade patterns required to reduce the deficit for one segment of the Egyptian economy. The reasonableness of these results rests upon the accuracy of the data used and the appropriateness of the assumptions made.

Every researcher must select the data deemed suitable for analyzing the problem to be solved. Frequently, the information is less satisfactory than desired because some aspects of the problem cannot be quantified, some data relate only indirectly to the variables in the model, some data are subject to considerable measurement error. That is the situation confronted in this study.

The import and export prices may be the least reliable of the input data. They relate to the season averages for all quantities imported and exported. For several crops they can be accepted as fairly accurate data. For other crops, such as horticultural products, they are less satisfactory. Fewer price data may be gathered for crops sold in smaller volume. Prices may fluctuate widely during the course of a season. Price differentials may vary considerably among varieties, quality grades, sizes, etc. Most exports and imports are sold to or from several countries. Such transactions may be completed in various currencies. Exchange rates vary over time and change among countries. Converting to Egyptian pounds can become difficult.

Data on the use of imported production inputs for individual crops are unavailable. The estimates used are derived from the value of fertilizers, insecticides and machinery imported by Egypt. These national totals were allotted among individual crops using assumed per-feddan rates supplemented by

other information. The water data also are estimates derived from assumed rates of application. However, these are subject to less measurement error.

Quantities of production, imports, exports and domestic consumption are relatively accurate. Converting the tonnage amounts to feddan equivalents does present a problem in some case since national average yield are used for this purpose. For example, only one-third of the domestic consumption of wheat comes from local production. Converting imports to equivalent feddans at the average Egyptian yield may not be warranted. A large expansion in local production (to offset decreased imports) might alter the average yield substantially. A second example indicates a different situation. A grower of a crop for export may have a yield much higher than the average because he employs better cultural practices, plants more productive varieties, etc. On the other hand, his yield could be lower because he produces for the off-season market, grades his output more severely with the expectation of a higher price.

As indicated, data for several series (especially those appearing in Table B) are mere estimates, derived by piecing together fragmentary information from several sources. For this reason, rounded figures are used for all data. Hence the input data generally are significant to only two places. It is believed, however, that the results obtained do not need to be qualified severely for this reason. Furthermore, they can serve as reasonable first approximations of guidelines used for indicating the direction in which changes should be made for reducing the unfavorable balance of trade now facing Egypt.

The basic linearity assumption of linear programming is accepted. In other words, technological and economic relationships are assumed to be linear over the range of changes in the decision variables required to shift

to the optimum solution. The shifts are not of a large magnitude and hence it seems likely that using linear functions is justified at least as first approximations.

Various other assumptions are made--some explicitly, others by implication. Each of these need not be discussed here. The following comments are limited to five.

Domestic consumption for each crop is retained at its current level because the study is directed at reducing the current unfavorable balance of trade. Nevertheless, the results include shadow prices which indicate how changes in domestic consumption affect the trade deficit. These unit costs vary widely. They could be used to justify attempts to alter consumption among crops. However, other factors need to be considered also: impact on health, consumer preferences, the food security program, etc.

The potential expansion of foreign exports is assumed to be about 10 percent for crops now exported. The optimal solution increases exports to the limits set. Furthermore, the sensitivity analysis indicates that much larger quantities could be exported provided relative prices for exports and imports were not changed materially. This result is of practical importance. It means that exports of these crops should be encouraged, even though it means increasing the imports of other crops.

Constant yields, at national averages for 1976-1979, are used for converting all tonnage data to equivalent feddans of land area. Such yields, however, do vary, sometimes considerably, for different segments of each crop. The assumption may have a larger effect than expected.

It was assumed that water availability is at 10 percent above current use. Setting the limit lower would change the optimal pattern of land use. An attempt was not made to determine the extent or magnitude of this change.

It seems likely that the use of land for sugarcane, rice, and oranges might be reduced since these crops are heavy users of water on a per-feddan basis.

The interdependence and conflicting objectives of different sectors of the economy may represent major obstacles to achieving the optimum pattern of foreign trade. International competition, marketing constraints, and lack of marketing information could become bottleneck to improving Egypt's balance of trade. The desirability of a country's attempt to increase exports is conditioned by several factors, such as the technical knowledge of its farmers, their use of good technology, and the use of crop rotation. There may be considerable competition among objectives being sought. For example, a cropping pattern which ranks high for export earnings may rank low in terms of food security.
