## I. INTRODUCTION

Recent indicators show that the agricultural sector in Egypt is moving in a direction where it will increasingly fail to meet future dowestic (food) and export (foreign currency) 'demands.

Development and administration of natural resources in Egypt since 1952 has been largely the responsibility of the government, through the Ministry of Agriculture.

The current agricultural problems have reached such levels of magnitude, that public intervention is still justifiable, particularly in light of the fragmentation of holdings by the private sector. Conflicting objectives within the public and private sectors have led to several problems. Examples are urban sprawl, natural and man-made (brick manufacturing) erosion, avoiding the centrally administered cropping pattern, declining production of export-revenue earning crops such as cotton, rice and onions, and possible misallocation of scarce land and water resources.

If agriculture is to continue as a major contributing sector to the economy, immediate attention is required on the various problems. In the context of development planning and, in light of the current trends, it seems rational to first tackle issues of policy and pricing as these are central to a solution to the other problem areas.

The general goal of the research project could be broadly categorized as being empirically oriented, in that it investigates the effects on the cropping pattern and other parameters of agricultural production of a relaxation of the tight restrictions imposed by the administered price system. The last few years have already witnessed a gradual move towards allowing relatively larger margins of profit to the farmers.

This report opens with a description of the design, construction, and estimation of the model. Then, the results of the analysis are examined; and, finally, a discussion of the findings and their implications is made.

The objectives of this paper are to: (1) demonstrate the construction of a recursive linear programming model to be used as a vehicle for investigating land and water allocation; (2) measure the potential gains due to a higher degree of regional specialization; and (3) investigate the effects of an alternative pricing policy for the four main controlled crops.
II. MODELLING THE AGRICULTURAL SECTOR

The principle of including a time lag (or time delay) mechanism in models has led to the evolution of dynamic analysis. That in turn led to the increased complexity of models. Computational procedures have attempted to meet the challenge by breaking down inter-temporal optimization problems to smaller problems of suboptimization with feedback. The feedback mechanism is incorporated in the values of both $x(t)$ and the constant a in

$$
\begin{equation*}
x(t)=a^{2} x(t-2)=a^{h} x(t-n)=a^{t} x(0) \tag{1}
\end{equation*}
$$

where $x(t)$ is the variable of interest at time $t$.
During the actual process of solution, new observations always occur and it thus becomes inevitable that $a^{t}$ should be allowed to vary, thus (1) becomes:

$$
\begin{equation*}
x(t)=a^{t} x(t-1)=a^{t} a^{t-1} x(t-2)=\cdots \prod_{j=0}^{n-1} a^{t-j} x(t-h) \tag{2}
\end{equation*}
$$

Furthermore, since $a^{t}$ is affected by the values of $x(t)$ prior to period $t$ we get

$$
\begin{equation*}
a^{t}=f_{t}(x(t-j)) \tag{3}
\end{equation*}
$$

which on substitution in the first-order homogenous linear difference equation $[x(t)=a x(t-1)]$ gives

$$
\begin{equation*}
x(t)=h_{t}(x(t-1), x(t-j)) \tag{4}
\end{equation*}
$$

This implies that the value of $x(t)$ is partially determined by the initial condition $x(0)$ and implicitly by the value of each allocation between $x(0)$ and $x(t-1)$. It should also be stressed that (1) and (2) above, are dissimilar since the former is analogous to the principal of optimality of dynamic programing in that no allowance is made for revision and renewal of parameters and data after an optimal decision has been made, whereas the latter is
"a sequence of optimizations with feedback ... which... may converge to a path that is intertemporally optimal in some sense; just as a sequence of atonement like adjustments may lead to a general equilibrium that is efficient or Pareto optimal." (Day, 1977, p. 83)
Cournot (1838) utilized the feedback principle in his duopolies study, but it was not until Wood (1951) that restrictions were placed on the levels of a solution's activities. These restrictions were in the form of a statement that an activity in any time period shall not exceed $(1+\alpha)$ of its value in the previous period. It was Day, however, who in 1963 explictly incorporated this restriction in a mathematical program which he also called recursive programming. This was done in Day's adaptation of Henderson's 1959 national model, to the Mississippi Delta area. The latter was the first though, to mention that his "... analysis is both descriptive and recursive" (p. 242).

About the same time as Henderson's endeavors were completed, Nerlove (1958, 1959) was discussing the lags in price response. This work contributed to the philosophical foundations of this class of models. The idea of adjustments of production in response to exogenous variables had been studied earlfer (as early as Marshall) by Hicks (1953) whose "responses" were due to price expectations.

Henderson integrated several ideas to develop his analysis. He used a combination of lag models, production response, restrictions on activities, and linear programing. The farmer's decision making process was recognized as dependent on two forces. The first is profit maximization. The second could be stated as a restriction on maximizing net returns in that a multitude of factors, economic, sociological, personal, technical, and institutional are combined to limit the decision to deviations from preceding ones and not just emerging as fresh "unrooted" decisions. Thus the relation

$$
\begin{equation*}
\left(1-\beta_{i j}, \min \right) x^{\star}{ }_{i j} \leq x_{1 j} \leq\left(1+\beta_{i j, \max }\right) x_{i j}(j=1, \ldots m) \tag{5}
\end{equation*}
$$

in which $x_{i j}{ }_{i j}$ is the acreage which the $1^{\text {th }}$ farmer devoted to the $j^{\text {th }}$ crop in the preceding crop year. The $B$ coefficients are "constants for the determination of the farmer's current land utilization pattern" (Henderson 1959, p. 243). Estimates of the constants were made by separately averaging the positive and negative historical crop acreage movements.

An important question still has to be answered, why use flexibility restraints? Before attempting to tackle the question, perhaps it is helpful to reiterate that these bounds barely allow for aggregate measurement of disaggregate activities. This fact was highlighted in Cigno's (1971) study of the effects of the Common Agricultural Policy of the EEC on Italian Agriculture. A policy maker has to recognize that:
(1) Only a subset of farmers adapt quickly to changing market conditions because they anticipated them, while the others walt until price changes reduce them to adopt a new system.
(2) Only a subset of farmers foresee a more profitable mode of production and thus have a fast adoption rate, while others only change when it is apparent that profit is manifest in the proposed price changes.
(3) Certain products will only increase in production up to a certain level to which we add a fourth point.
(4) In the presence of ministerial targets and acreage quotas, it is only realistic to limit changes in production to these levels which will be allowed in reality.

Going back to the question, flexibility restraints merely translate all these considerations into a model component. Thus, once incorporated into the model, these restraints will effectively limit our solution. These limitations lead to inevitable residuals because it is impossible to simultaneously satisfy all the upper and lower bounds. For this model the crops were stratified as follows:
(1) Crops which do not directly compete with other crops for area (within the rotation) such as sugar cane.
(2) Crops which are in direct competition for area with other crops. Usually these fall into the same subdivision within the crop rotation program such as rice and maize.
(3) Crops which are indirectly competing for area with other crops, such as cotton and berseem. Even though these crops do not follow the same seasonal category, berseem could be extended into cotton planting time and it thus affects cotton yields and production.

The actual process of measurement of the flexibility coefficients is therefore a function of the previous points, farmers' response, crop categories, and estimation considerations and techniques. The sought relation is in the form of:
(1) Upper bounds $X_{i t} \leq\left(1+\bar{\beta}_{1 t}\right) X_{1 t-1}$
(2) Lower bounds $X_{1 t} \geq\left(1-\underline{B}_{1 t}\right) X_{i t-1}$

A programming model was selected as most suitable because of the spatial nature of production and its implications for interregional specialization; in addition, the homogeneity of Egyptian agriculture allows such an approach. Programming models are normative, and it is usually the case that models of agriculture purport to change regional production patterns. In the agricultural decision making process, a recursive element is inherent because decisions for a particular period are influenced in part by previous ones. Also, decisions are continuously being amended due to updated information, a feature which could be easily incorporated in an RP. Furthermore, in an RP the parameters of a multi-period model can be adjusted in response to the previous solutions. That feature is particularly useful for accommodating technological change in the models. But the fourth and (probably) foremost advantage of $R P$ over LP is due to Henderson's identification of the factors affecting farmers decisions as including some nonpecuniary elements. However, by relying on measurement of previous reaction to similar conditions (similar in principle but not necessarily in magnitude), one can specify the range within which the response is likely to happen. This is the spirit of RP as represented by the flexibility restraints. RP's are dynamic in a Frisch-Samuelson sense because the parameters are time subscripted in an Irremovable way.

The model could be written as: ${ }^{1}$

$$
\begin{gather*}
\max z=c^{T} X  \tag{6}\\
\text { subject to } A x \leq b  \tag{7}\\
x \geq 0 \tag{8}
\end{gather*}
$$

where $A=$ an $m \times n$ matrix
$x=a n$ n-element column vector
$b=a n$ m-element column vector
$c=a n$ n-element column vector.
In the above system if time is introduced in an irremovable way, i.e., the solution for time $t$ is only possible after that for $t-1$ is reached, RP, the model, has the formulation as follows:

$$
\begin{gather*}
\max Z(t)=C^{T}(t-1) x(t) \quad t=1, \ldots, n  \tag{9}\\
\text { subject to } A x(t) \leq \theta A x(t-1)+k  \tag{10}\\
x(t) \geq 0
\end{gather*}
$$

where $\theta=$ an $m \times s$ diagonal matrix such that

$$
\begin{align*}
& \left(1-\beta_{1}\right) \\
& \left(1+\bar{B}_{n}\right)  \tag{11}\\
& \left(1-B_{i}\right) \\
& \left(1-E_{n}\right)
\end{align*}
$$

${ }^{1}$ The superscript $T$ indicates the transpose of a matrix. The vectors are column vectors.
and $k=a n m \times l$ vector of fixed resources such that

$$
k^{T}=\left[\begin{array}{lllll}
\bar{x} & 0 & 0 & \ldots & 0
\end{array}\right]
$$

and $c(t-1)$ is composed of $n$ net returns. The matrix $A$ is structured as follows:

and $x(t-1)$ is of dimensions ( $n \cdot 1$ ) and is composed as follows:

$$
x(t-1)^{T}=\left[\begin{array}{llll}
x_{1} x_{2} & \cdots & x_{n}
\end{array}\right]
$$

The right hand side vector in (7) is thus a function of lagged endogenous and current exogenous variables, which fall into any of these categories:
(i) resource supply, such as land, water, labor, fertilizer ..., etc., (ii) ceilings on activities such as the upper and lower flexibility restraints, and (iii) managerial constraints which take the form of budget constraints, minimum production levels, investment requirements ..., etc. Thus, essentially the system

$$
\begin{equation*}
A x \leq b \tag{13}
\end{equation*}
$$

is a production transformation set. That is clear from the solution to the model since the matrix A transforms inputs into outputs via the yields (or $a_{i j}$ 's) which in time are transformed into activity levels at the optimum $\left(x^{*}\right):$

$$
\begin{equation*}
A x^{*} \leq b \tag{14}
\end{equation*}
$$

where $x^{*}$ is the vector of optimal solution process levels. Additionally, the matrix A also transforms the input requirements into an input demand relationship. Thus, at the solution stage, the system becomes:

$$
A x_{t}=\left[\begin{array}{l}
Y_{t}  \tag{15}\\
V_{t}
\end{array}\right]
$$

where $Y_{t}$ is a vector of output supply and $V_{t}$ is a vector of input demand.
If the third component of the constraints set is expanded, i.e., the budget constraints, it results in:

$$
\sum_{j=1}^{m} a_{1 j} x_{j t} \leq b_{i t}
$$

where $b_{i t}$ is the budgetary allowance defined as operating surplus which is the difference between revenue and cost, and thus:

$$
\begin{equation*}
\sum_{j=1}^{m} a_{1 j} x_{j t} \leq \sum_{j=1}^{m} P_{j t-1} X^{*}{ }_{j t-1}-S_{t} \tag{17}
\end{equation*}
$$

where $P_{j t-1}$ is used as a proxy for expected price and the revenue is formulated in terms of $t-1$, while the cost $S$ is assumed to be estimable for t. By substituting (9) into (15) we obtain:

$$
\sum_{j=1}^{m} a_{1 j} x_{j t} \leq\left(a+B X_{t-1}\right)^{T} X_{j t-1}^{0}-S_{t}
$$

which in conjunction with (12) defines the new system that is now "closed"

$$
\begin{equation*}
\operatorname{Max} z=a^{T} X_{t}+\left(x_{t-1}^{0}\right)^{T} B^{T} X_{t}-K_{t}^{T} X_{t} \tag{19}
\end{equation*}
$$

subject to

$$
\begin{gather*}
\sum_{j=1}^{m} a_{1 j} X_{j t} \leq a^{T} X_{t-1}+X^{O T}{ }_{t-1} B X_{X-1}^{0}-S_{t}  \tag{20}\\
\sum_{j=1}^{m} a_{1 j} X_{j t} \leq b_{1 t} \quad(i=2, \cdots, n)  \tag{21}\\
X_{j t} \geq 0 \quad j=1, \cdots, m
\end{gather*}
$$

The system is closed since the solution for period $t$ is a direct function of that for $t-1$, hence it is recursive. The corresponding dual is

$$
\begin{equation*}
\min \Psi=\left[a^{T_{x}}{ }_{t-1}+X_{t-1}^{0 T_{t-1}} T_{X}^{0}{ }_{t-S_{t}}\right] \lambda_{i t}+\sum_{i=2}^{n} b_{i t} \gamma_{i t} \tag{23}
\end{equation*}
$$

subject to

$$
\begin{gather*}
A^{T} \lambda_{t} \geq a+B X_{t-1}^{0}-K_{1}  \tag{24}\\
\lambda_{t} \geq 0 \tag{25}
\end{gather*}
$$

The model presented above is outlined in tableau form by Table 1. The upper and lower bounds were specified on a regional basis rather than a governorate basis to allow a greater degree of regional specialization. If the constraints were specified on a governorate basis the fell ramifications of alternative specification are restricted because only small changes in acreage within governorates would be permitted. The model thus specifies an upper and lower bound for every crop for each of the three regions (or groups of governorates) which are traditionally pooled as:
I. North 1. Alexandria
2. Behera
3. Gharbiya
4. Kafr El Sheikh
5. Dakahliya
6. Damietta
7. Sharkiya
8. Ismailiya
9. Suez
10. Minufiya
11. Kalyubiya

19. Aswan

The yield entries ( $Y_{i j}$ ) were obtained from Ministry of Agriculture (MOA) estimates of average yields and may contain a sampling error or departure from "time" yields. Water coefficients ( $w$ ) were generated by aggregating several sources reporting water wages and water requirements. This data, reported per crop, per season, or per area, had to be processed into a per feddan basis.

The regional recursive linear programming model measures several parameters both at the national and regional levels. These are agricultural net revenue, crop production, demand for inputs, and resource valuations. The formulation of the model makes it possible to assess the two main goals of the exercise. First, net revenue is maximized subject to water supply by region, land productivity by governorate, the avallability of purchased and nonpurchased inputs, crop rotations, regional governmental and public policy, behavioral constraints, and the current technology. The second objective was to gauge the system's reaction to several proposed changes over time, such as price and nonprice intervention, regional specialization, resource policies, and deteriorating land quality because of rising water tables. For the 30 crops included in the model, production activities are specified by governorate. The data in the model is on an annual basis, thus
we have yield per feddan, price per unit of product, variable and fixed costs, water supply, labor supply, fertilizer input, machinery input, animal input and the various behavioral constraints (flexibility constraints). The matrix of technical coefficients is of size $845 \times 1777$, and its 9251 elements are basically of two types, yransfer (pivot) elements and input coefficients for the various resource requirements.

The objective function could be expressed algebraically as follows:
$\operatorname{Max} \quad z=\sum_{j=1}^{k+\frac{m+n}{q+i+s}}\left[\left(P_{i=1} Y_{i j}\right)-C_{i j}\right] X_{i j}$
where $C_{i j}=\sum_{y=1}^{b}\left(m_{y} L_{y}+t_{y} M_{y}+a_{y} A_{y}+V\right)+d_{i j} F_{i j}+l_{i j}$
and
$Z=$ agricultural aggregate net revenue from plant production
$P_{i j}=$ price per unit of output of crop $i$ in governorate $j$
$Y_{i j}=$ yield per feddan of crop 1 in governorate $j$
$C_{i j}=$ total cost per feddan in LE for producing one feddan of $i$ in $j$
$X_{i j}=$ number of feddans of crop 1 in $j$
$m_{y}=$ wage rate per man hour in month $y$ for labor $L_{y}$ hired for growing in $j$
$t_{y}=$ machine cost per hour in month $y$ for machine time $M_{y}$ employed in producing $i$ in $j$
$a_{y}=$ cost of feed per draft animal in month $y$ for animals Ay working in producing $i$ in $j$
$d_{i j}=$ cost per kilogram of fertilizer $F$ employed in producing $i$ in $j$
$1_{1}=$ rent per season 1 per feddan
$\mathrm{v}=1 \mathrm{~s}$ other additional cash outlays
$\theta=k, m, n$ are north, middle and south, respectively
$\alpha=q, r, s$ are winter, summer and nili, respectively
$b=1, \ldots, 12$ is the months of the year.

Regional crop production and net revenue are maximized subject to several constraints:

$$
\begin{align*}
& \sum x_{i j} \leq \bar{x}_{j}  \tag{28}\\
& \sum_{i} X_{i j} \leq \bar{X}_{j}{ }^{w}  \tag{29}\\
& \sum_{1} X_{i j} \leq \bar{X}_{j}{ }^{s}  \tag{30}\\
& \alpha \theta \\
& \sum_{1} \sum_{j} X_{i j} \leq \bar{X} \tag{31}
\end{align*}
$$

where
$\bar{X}_{j}=$ the total number of feddans in governorate $j$
$\bar{X}^{k}{ }_{j}=$ the maximum number of feddans available for winter crop production (including land for permanent crops in the winter months)
$\overline{\mathrm{X}}{ }_{j}=$ the maximum number of feddans available for summer and nili crop production (including land for permanent crops in the summer months)
$\bar{X}=$ the total national cropped acreage available in all regions.
The set of constraints specified by (28)-(31) relate to the land constraints within which optimization is to take place. The winter and summer acreages were formulated from data on the base period. The water supply is specified through

$$
\begin{equation*}
\sum_{i}^{\alpha} \sum_{j}^{\theta} \gamma_{i g y} x_{i j} \leq \bar{w}_{y}^{0} \tag{32}
\end{equation*}
$$

where $\gamma_{i j y}=$ the quantity in cubic meters required to produce crop i in Governorate $j$ in month $y$.
$\bar{W}=$ the total amount of irrigation water available in cubic meters in region $\theta$ for month $y$.

The human labor requirements are estimated and expressed as:

$$
\begin{array}{ll}
a & \theta \\
\Sigma & \Sigma b_{1 j} x_{1 j} \leq \bar{L}_{j}  \tag{33}\\
i & j
\end{array}
$$

where $\bar{L}_{j}$ is the available labor in governorate $j$ expressed in man hours.
$b_{i j}$ is the requirement per feddan of crop 1 in governorate $f$ of labor. The final set of constraints on physical inputs is the one which covers fertilizers, machinery, and animal input.

$$
\begin{align*}
& \alpha  \tag{34}\\
& \Sigma \sum_{j} f_{i j} \\
& X_{i j} \leq \bar{F}_{\theta}
\end{align*}
$$

where $\bar{F}_{\theta}$ is the total available supply of nitrogen fertilizer in region $\theta$.

$$
\begin{align*}
& \alpha  \tag{35}\\
& \sum \sum_{i}^{\theta} \varepsilon_{i j} X_{1 j} \leq \bar{M}_{\theta} \\
&
\end{align*}
$$

where $\bar{M}_{\theta}$ is the total available machine hours in region $\theta$.

$$
\begin{align*}
& \alpha \theta  \tag{36}\\
& \Sigma \\
& i j \\
& i
\end{align*} v_{i j} x_{i j} \leq \bar{A}_{j}
$$

where $\bar{A}_{j}$ is the available draft animal expressed in animal days for governorate $j$, and $f_{i j}, \varepsilon_{i j}, v_{i j}$ represent the technical requirement per feddan of nitrogen fertilizer, machine hours, and animal days, respectively. The above constraints are in addition to the flexibility constraints discussed earlier.

$$
\begin{align*}
& \sum_{i} \sum_{j=1}^{N} x_{i j} \leq\left(1+\bar{\beta}_{1 d}\right) x_{i j}(d-1)  \tag{37}\\
& \sum \sum_{j=1}^{N} x_{i j} \geq\left(1+B_{i d}\right) x_{i j}(d-1) \tag{38}
\end{align*}
$$

where $\bar{B}_{1 d}$ is the upper flexibility coefficient for crop i in region $N$ or $M$ or $S$ for year $d$.
Bid is the lower flexibility coefficient for crop in region $N$ or $M$ or $S$ for year d.

III. ESTIMATION OF THE MODEL

The model passed through several stages of building and testing before it arrived at its current form. The first stage in model building was the design of the structure in such a way that future augmentation would be possible. The overall system was to be put together to achieve the end objective of creating an experimental vehicle which would aid in analyzing the agricultural sector, and then, investigating the effects of any postulated changes. An integrated system presented in Figure 1 is still incomplete, mainly because of the lack of reliable elasticity measures which are needed for the price forecasting equations. Thus the prediction model (the second in the figure) has not been formulated. The first use of the model, the Regional Recursive Linear Programming Simulation Model (RSM) provides estimates of the values of resources, the cost of some policy actions, and identifies resource and input use under current conditions. The third model, which is the Regional Parametric Recursive Linear Programming Policy Model (PPM), can estimate derived demand relationships for inputs, investigate policies affecting resource use and stocks, and gives an alternative assessment of the marginal value of resources under altered output values.

The basic model uses the type of flexibility coefficients proposed by Day on crop acreages on a regional basis. Within the three regions, crops are allocated to governorates according to their cooperative advantage. The bounds serve as the effective limits on the optimization process and thus ensure that we are "close" to reality.

In making any comparisons between the model results and the actual cropping pattern, the model will give some indication of comparative advantage in crops among governorates through the dual values on the bounds
and crop activity rows. Although the model does in principle reflect the influence of administered prices and production plans and targets, it will not necessarily reflect every aspect of public policy at governorate level. One should also note that allocations not only reflect margins of net returns, but also the pattern of resource use and marginal productivity differences. So an estimate of productive efficiency vis-a-vis national requirements can be estimated for input use. The salient inputs are land, water, labor, fertilizer, animal power, and machinery.

The Price System was run recursively for the years 1975-79, using prices which are higher than the actual prices for the period. Table 2 lists the objective function values for the sequence of Price models, and for the historical (henceforth referred to as Original) equivalent. The figures are aggregate values added resulting from crop production in current Egyptian pounds (L.E.).

Table 2
Value Added Estimates in LE ${ }^{1}$

| Year | Original | Price System |
| :--- | :---: | :---: |
| 1974 | $569,847,870$ | NA |
| 1975 | $585,404,350$ | $1,204,509,879.98$ |
| 1976 | $619,620,230$ | $1,195,245,297.67$ |
| 1977 | $705,843,400$ | $1,539,412,085.38$ |
| 1978 | $745,976,690$ | $1,969,818,151.48$ |
| 1979 | $1,167,382,600$ | $2,315,067,399.36$ |

${ }^{1}$ Nominal Prices
The 1975 and 1979 years are the only ones to be discussed in detail for several reasons: (i) they are the opening and closing years of the sequence (although most of the results for the other years will be presented, but not discussed in the same detail); (11) 1975 is the first year, so no recursive
error build-up is included; (111) 1979 is the last year, so it should include the effect of any accumulated error, and the effect of successive optimizations; (iv) 1979 is also the most recent year to be analyzed and as such is important to our discussions; (v) As far as model validation is concerned, these two years should be sufficient; and (vi) it allows us to determine the various characteristics of the 1975 solution (such as allocational inefficiencies) and then by studying 1979 we could determine the pattern of change.

Running the price system consisted of changing the prices of the four major crops: cotton, wheat, rice and sugar cane.

Table 3 shows the international and local prices for these crops, together with the tax implied by the price differentials. The table shows that the tax has been declining, but a detailed look will show that a large part of the decine is due to the drop in international prices, and thus the typical farmer is still faced with the problem of insufficient incentives. In the face of that reality, the margin between both prices was halved (i.e., reduce the inputed tax by half). Table 4 gives the new prices and the percentage change over existing prices.

The net return estimates listed in Table 2 are in nominal prices and include the effects of various factors such as inflation, the effect of the optimization process, and the price effect on the various model parameters. To be able to separate these effects, we ran a sequence of models called Day system which is identical to Price system except that it uses the actual prices in the objective function. Computing the objective function value (aggregate net returns) for all three systems (Original or historical, Day system, and Price system), using 1979 average crop prices would remove the

Table 3
International and Local Prices
for Major Crops 1975-1979

| Crop | 1975 | 1976 | 1977 | 1978 | 1979 |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Cotton |  |  |  |  |  |
| International price | 84 | 70 | 96 | 73 |  |

Notes

1. International prices are adjusted for transportation, processing, etc.
2. All prices are in Egyptian pounds per unit of net product (i.e., sugar cane prices are for the sugar equivalent) based on the appropriate conversion factors.
3. The tax figure is the difference between both prices represented as a percentage of local prices.

Source: computed from MOA and FAO statistics.

Notes

1. All margins were halved except for rice and wheat in 1975 where the new price is based on 33 percent of the difference plus the old price.
2. These prices are only averages for the whole country but the actual price scenario figures vary between governorates.
effect of inflation. We would then be left with the other two factors. The difference between the Day and Original systems represents the effects of optimization within the flexibility constraints, and the difference between the Price and Day systems represents the effects of the higher prices. The aggregate crop net returns have been recalculated using the 1979 national average price for each crop, and the new values are presented in Table 5.

Comparison of the totals in the table reveals that the Day system's aggregate net returns in real terms for 1975 was only an improvement of . 02 percent over the Original figure, compared with 12.82 percent when measured in current prices. For 1979, the Day system'sl estimate in current prices was 43.46 percent higher than the original estimate, whereas when evaluated in real terms, the difference became 13.93 percent. The difference is not all due to deflation or the actual effect of optimization, but is also due to the fact that for every crop, the weight used is an average for that crop, whereas in the model the net return valuations are computed for each crop/governorate combination and thus have a wider variance. Nevertheless, we can still say that these results show that in aggregate terms, restructuring the production process within the flexibility constraints did not show large efficiency gains in real terms. The inputed costs of some of the constraints will be examined later. However, if we view the situation from a dynamic context (over several years), we find that the agricultural system will take a few years to adjust. For example, the improvement due to higher prices in 1975 is marginal (.9 percent) ${ }^{2}$ when measured in real terms, compared to a

striking 105.6 percent using current prices, which even when adjusted for the effect of optimization (to give us the effect of higher prices) gields differences of .87 percent and 92.78 percent, respectively. Or in other words, on the surface the picture looks really rosy with a doubling of agricultural returns by changing some prices (not dramatically), but in real terms the initial benefits are substantially lower than some other unconstrained studies have estimated. One should only expect a real shift in returns to the tune of $10-13$ percent in response to higher prices in the first year of change. At the end of several years, when the prices have been brought closer to the equilibrium values, we can expect the real change to be about 30 percent ${ }^{l}$ (compared to 95.67 percent). Again, the price effect alone is 31 percent and 52.21 percent (real and current, respectively). The situation could be summed up as follows: If a reorganization is made such that we can reallocate production within regions to achieve a more efficient pattern and also to reorganize such that the more optimal crops are emphasized, then we can expect an improvement in aggregate net returns of about . 02 percent in the first year, but over time the change becomes 14 percent at the end of the fifth year of pursuing such a policy. Additionally, if we use higher prices for the four major crops, we can expect an increase of about .9 percent in the first year, which rises to 30 percent at the end of the fifth year. More dramatic gains in reallocation of production may result if interregional shifts in key crops is permitted. This substantial institutional shift is not examined in this set of results. So far, only total figures have been discussed, but examination of the net returns when disaggregated by crop will show what the effects would be in a

[^1]more detailed fashion. These effects could be broken down further into acreage effects (i.e., the change in area and production) and price effects (1.e., the nominal effect of higher prices). First, we can look at the price effect before and after deflation by the 1979 weights. We already examined the deflated net returns in Table 5 , and the undeflated results are presented in Table 6.

These results are really quite interesting, since for example one could be easily misled into thinking (indeed as several analysts have done) that by doubling cotton price (for example), its aggregate net return would rise from L.E. $82,509,187$ (original 1975 NR) to L.E. $238,546,690$ (Price 1975 NR ); but if we reevaluate these figures using the 1979 NR as weights, the change is only from L.E. $240,407,270$ to L.E. $248,688,530$, that is, a change of only 3.4 percent compared to a nominal increase of 189.11 percent. For rice, the nominal increase is from L.E. $39,383,857$ to L.E. $236,845,585.9$, while in real terms it is only from L.E. $60,322,242$ to L.E. $68,501,174$ in response to a price change of 183 percent. Doubling the price of wheat still doesn't seem to make any difference since the adjusted net revenue (NR) actually drops from the original adjusted L.E. $15,626,180$ to L.E. $13,669,653$, while in nominal terms the original is L.E. $45,415,099$ and the Price 1975 NR is L.E. $130,591,360$. Also, doubling the price of sugar cane caused the real $N R$ to change from L.E. $39,059,000$ to L.E. $41,219,011$, whereas the nominal change was from L.E. $34,598,229$ to L.E. $92,724,178$.

For 1979, the effects of the Price change at the end of the five year phasing-in is also affected by the fact that the original NR valuations

1 By that we mean the effect of prices in an accounting sense.

include the effects of several actual price increases. Thus for the four major crops under investigation, their Price 1979 prices are the last stage in narrowing the gap between local and international prices, while for Original 1979, this is also true, although to a lesser extent, since Original 1975 does not include any higher prices while in 1979 the actual prices were higher in real terms.

For cotton in 1979 we find that at first glance the net returns of the Price model are L.E. $210,837,290$ which are approximately equal to the original L.E. $213,533,430$, while after deflation the Price estimate becomes L.E. $159,938,650$. Rice also drops from the L.E. $131,770,498$ estimated by Price 1979 to the adjusted figure of L.E. 72,637,346 while the original estimate is L.E. 59,702,574. The original figure for wheat is L.E. $15,529,135$ which when compared to the adjusted figure of L.E. $6,026,659.5$ while in nominal terms the reduction is only to L.E. $10,549,753$. Sugar cane also dropped from the original L.E. $44,356,107$ to the adjusted L.E. $32,289,908$ while the unadjusted is L.E. $41,154,875$. Note, however, that the totals for 1979 showed an increase in both nominal and real terms from L.E. 1,176,842,600 to L.E. $2,315,067,000$ and L.E. 1,711,022,900, respectively, which is largely the effect of the acreage increase in the crops with unaltered prices, such as peanuts, garlic, summer sorghum, nili sorghum, summer potatoes, nili potatoes, winter tomatoes, summer tomatoes, nili tomatoes, winter vegetables, sumner vegetables, nili vegetables, melons, and summer onions. For 1975, in addition to the real increase in net revenue brought about by increasing the prices of the major crops (except cotton which marginally dropped), the following crops also increased: lentils, barley, flax, nili sorghum, winter onions, summer potatoes, winter tomatoes, summer tomatoes, oranges, and summer onions.

The changes in these crops for 1975-79 are not due to the cross price effect since when no price changes are made (as in the Day models), the list of crops for which net returns have actually increased is mainly due to the effect of optimization. Thus for 1975 the list is: peanuts, lentils, beans, garlic, sesame, summer sorghum, nili sorghum, maize, winter onions, summer potatoes, nili potatoes, winter tomatoes, sumer tomatoes, winter vegetables, summer vegetables, nili vegetables, melons, and summer onions. Thus we can say that the cross price effect is due to the difference in both lists, i.e., the decrease in net return due to the change in the following crops: peanuts, beans, garlic, sesame, summer sorghum, maize, nili potatoes, winter vegetables, summer vegetables, nili vegetables, and melons. For 1979, the price effect is attributed to: lentils, beans, winter onions, maize, long berseem, melons and summer onions.

This analysis leads us into examining the acreage effect (both non- and cross-) due to the price changes. This could be achieved by examining Table 7 and comparing it to Tables 10 and 11 . The comparison confirms that the Day system shows a drop in acreage for cotton in all three regions; that is, on optimality grounds the areas we actually measured in the original time series are not the time equilibrium values. Then, when the Price system is operated, the areas actually approximate (marginally higher than the original) true areas, indicating that these prices are closer to the prices that would lead to such acreage. The question is then which method is more acceptable, the price incentives or the employed quota system? The answer is implied in the original acreage tables where we can see that the general trend for the acreage of several crops has been dropping, which indicates the desire of farmers to change their production pattern (where the crops are administered,

but where they are not, it is an indication of the direction of the market forces). Tables 8 and 9 present the absolute and percentage difference (respectively) in the Price System areas for 1974-79.1

The breakdown of net returns by governorate is presented in Table 12 for 1975 and 1979. The effects of the higher prices on the per feddan net returns are presented in Table 12. The interesting feature of the change in net returns is that the higher prices seem to have caused a depression of agricultural income in some governorates, while the increase in the others more than offsets that drop as the aggregate net returns increase. This phenomenon highlights some of the features of the analysis, namely:
(i) Optimization models of this nature assume a higher degree of resource mobility than can be achieved. In this model, resources are defined by governorate except for water which is defined by region, but still this does not seem to be the cause of the problem. (ii) The optimization models work on optimizing some friction without regard to distributional effects which were deliberately omitted to allow efficiency effects to dominate. To this end we have succeeded in identifying which crops would be affected by a price increase for the major crops and in which areas.

The change in acreage on a Governorate basis can be gauged by comparing the acreages ${ }^{2}$ in Table 13 to those presented in Table 14 (for the Day system).

| 32 | 120 |  |  |  | 10 |  | 134 |  |  |  |  |  |
| 35 |  |  |  |  |  |  |  | 30 |  |  |  |  |

Some very interesting deductions can be drawn from such a comparison. For example, in the case of cotton in 1975 (or alternatively the first year of a price increase) the Northern acreage is concentrated in Sharkiya (534,616 feddans) and Dakahliya ( 336,406 ). But when the price is revised, the acreages change to Sharkiya ( 534,617 ), Gharbiya $(244,317$ ), and Dakahliya $(92,089)$ which is consistent with the Day system crop shadow prices. Table 14 shows that the next governorate to be expected to be used for expanding cotton acreage was Gharbiya. For example, in Suez the shadow prices show that the crops to be brought in next (if more land is to be used) are sesame and maize, which is exactly what happens since these crops are facing pressure from the now higher valued crops (the four major ones) in the most productive areas, which means that the displaced maize and sesame acreage is to be replaced elsewhere. This is why in Price 1975, Suez is producing those two crops in addition to its beans acreage. Examples of the shadow prices for the Price system crop rows and columns appear in Tables 15 and 16 for 1975. A shadow price of less than 20 percent of the price $1 s$ specified as being the maximum acceptable level for deciding whether to introduce a crop, when it is not specified in the solution. Under the price scenario advocated in Price system 1975, production of cotton is favored in the following Northern Governorates: Gharbiya, Dakahliya, Sharkiya (already selected by the model), and Behera, Kalyubiya, and Minufiya (based on above argument). Production in Kafr El Sheikh is not recommended (given the available information), and cotton should be discouraged in Ismailiya, Damietta, and Alexandria. The argument could be easily extended to cover all crops in all the Governorates for each year 1975-79.

The dynamics of the solution also provides valuable information since it demonstrates how the relative positions of governorates could change between years. For example, rice in 1975 under the price scenario is shown by the model to be produced in Behera, Kafr El Sheikh, Damietta. Ismalliya, Faymu and Garbiya, Dakahliya, Sharkiya, and Alexandria under the shadow price criterion ${ }^{1}$. For 1979 the list becomes: Kafr El Sheikh, Dakahliya, Sharkiya, Faymu (model selection) and Ismailiya, Alexandria and Beheira (shadow price criterion), while Damietta and Gharbiya have become marginally unfavorable. This then leads us to the conclusion that, once a governorate is proven acceptable for growing certain crops, it does not automatically follow that this advantage will remain indefinitely, even if the prices are raised relative to other prices.

The final aspects of the Price system to be discussed are the primal and dual values on the upper and lower flexibility restraints (bounds) since these values give us a marginal valuation of policy changes. For Day 1975, the crops at their upper bounds are the higher valued ones in general; thus the list includes: peanuts, garlic, sugar cane, sesame, nili sorghum, maize, winter onions, summer and nili potatoes, winter, summer and nili tomatoes, winter, sumer and nili vegetables, fruits, oranges, melons, and summer onions, although not in all three regions in every case. By revising the price of the four major crops in the Price 1975 run, the list becomes: cotton, peanuts, garlic, sugar cane, sesame, nili sorghum, maize, winter onions, summer potatoes, $n 111$ potatoes, winter, summer and nili tomatoes, winter, summer, and nili vegetables, fruits, melons, and summer onions, and again not
${ }^{1}$ This list for rice actually contains all governorates with the technical and climatic conditions favorable to rice, thus we see that $\qquad$ then is. uneconomic for rice production.
all crops have hit the upper bounds in all three regions. These lists identify which crops would tend to be favored for expansion and which would not (the complement of these crops out of the total crop list). However, the change over time is also of great relevance, and this information (dynamic movement $)^{1}$ is included in the tables on regional cropping activity. Limiting the results to the 1975 and 1979 models for both regions, the dual values are presented in Tables 17, 18, 19 and 20.

Examination of the dual values reveals that the price changes here indeed affected both the upper and lower bound duals.

1. Upper bounds: For the purposes of this discussion we must classify crops according to their market structure, i.e., either administered or free. In general, one would expect the administered crops not to be at their upper bounds (they are administered so as to keep their profit margins deliberately low as a means of subsidizing the industry and/or consumers). Applying the higher prices should help free these crops and move them towards their upper bounds, and since this uses up acreage that could otherwise have been used by other crops, one would expect that some of the other crops would move down from their upper bounds.

As an example, Table 17 shows that revising the prices for cotton and rice has caused them to be at their upper bounds (Price model) in the middle region. Also, revising the price for sugar cane has caused more pressure on its upper bounds since the dual value changed from 31.62 to 309.11 in the middle region and from 8.48 to 224.89 in the southern region.
${ }^{1}$ These are the primal values referred to earlier.

For the free crops group, one would expect that the effect of higher prices for the administered crops would cause that group's dual values on upper bounds to drop. The reason is that the higher prices (say) for wheat would cause its revenue to be relatively more attractive than before, compared to the free crops (but may be still less than for these crops); and, as such, wheat will be competing for land with these crops, which would cause their shadow prices to fall. This is true of all crops except for a few cases, namely sesame, summer sorghum, and summer onions in the middle region in 1975; and peanuts, sesame, fruits, oranges in the middle region in 1979. The reason seems to be due to the comparative advantage this region has for these crops. Looking at the cross-sectional change in these values by crop for each region indicates the most efficient crops. For example, in the south in 1975, the most efficient was $n i l i$ potatoes at a value of 384.86 , a situation which is also maintained under the price system.
2. Lower Bounds: These represent the cost of policy action, i.e., regional minimum acreage requirements, for the administered crops and the cost of demand for the free crops. One should expect the dual values to drop for the crops for which we raise prices, because there would be more incentive to produce them and less pressure to stop growing them. For the other crops, that price rise will cause their values to increase as the price incentive causes resources to start to be directed to the higher valued crops. This trend happened except in a few cases which for 1975 were northern cotton (increase in dual values instead of drop) and for 1979 northern cotton, barley, middle wheat, summer sorghum, maize, oranges, and southern cotton. The case for cotton is clear since by changing the price structure it seems that (even though its price has been raised) the other three major crops have
become more rewarding. So, for example, in the north in 1979, the dual value on cotton's lower bound changed from 8.96 to 10.39 , which means that it is even mor'e inefficient now (under the Price system) because the model would I'ike to reallocate its land to sugar cane with the highest value at 219.01 .

## IV. APPLICATION OF RESULTS

The estlmated results of our model, if they are to be useful (and usable), should now be examined in the context of actual policy. It is hoped that by now the reader has some appreciation of the overwhelming array of figures that the computer model has generated. There is no scope for presenting all the results here, let alone discussing and analyzing them; accordingly, only a subset of the results is presented.

A major problem that the results posed to analysis is due to the myopic optimization criterion of LP's, which resulted in only a subset of crops being grown in each governorate. This problem could have been tackled by adding more constraints to the model so that the number of allocated activities actually increases. Such a procedure would have posed enormous computational problems given the size of our model. The alternative was to improve our results a posteriori. This was done by using the shadow prices on crop activities to augment the list of crops grown in each governorate. If the shadow price was within 20 percent of the crop price, that crop was considered viable for production in that governorate. This 20 percent was considered to be a tolerance level representing nonpecuniary considerations or extra-model pecuniary variables. On that basis we modified the results through modifying the net return figures for each crop/governorate combination that did not get specified by the model but passed the 20 percent test. To achieve the
required results, considerable post-model calculations had to be made, a process which is extremely time consuming and tedious. This is why we will only present the figures for 1979, which are contained in Table 21. The acreage figures resulting from the model which altered prices is the cropping pattern to be expected under the new policy. That is, this is the response which, if farmers are optimizing, one would expect to see in reality. We have to add that optimization in this case is purely based on the interests of the sector. So, for example, the cotton acreage of 46434 in Kalyubiya might be considered too high for transporting its product to textile factories. On the basis of such arguments, government officials could alter the suggested pattern in favor of such additional considerations. On this conditional basis, the cropping pattern is optimal given the specified price changes. The results are by no means definitive, since they should be modified in three ways:
(1) The effect of endogenous demand prices for crops.
(2) Modifications to incorporate information not explicitly used in the model, such as transportation costs or location of demand (whether it is industry or urban population centers).
(3) Improvements in the method for handing the regional cropping mix.

Thus, the way in which a decision maker could utilize this approach is as follows: First, the suggested cropping pattern is optimized from the agricutural sector's point of view, based on considerations of private benefit and on returns to natural resources. Second, the central authority then evaluates the optimality of demand and linkages, for example, the setting of some crop processing plant.

Acreage Allocation Under Price Scenario
