## Abstract

This project employs economic models of fisheries harvest for commercial and recreational sectors in order to assess the efficiency of current catch allocations. We focus on catch of dolphin, king mackerel, red snapper, and a "grouper" species collection in the South Atlantic and Gulf of Mexico fisheries using commercial catch and recreational survey data. We utilize marginal values in each sector to identify allocations that maximize net economic benefits with consideration of biological and other constraints imposed by fishery management plans.

## Introduction

In this project we evaluate the economic effects of the allocation of fishery harvest among competing agents by estimating the net economic value to the commercial and recreational sectors. We employ the equimarginal principle to compare the desirability of alternative quota allocation scenarios for key species - dolphin, king mackerel, red quota allocation scenarios for key species - dolphin, king mackerel, red
snapper, and a "grouper" species collection - in the South Atlantic and snapper, and a "grouper" species collection - in the South Atlantic and
Gulf of Mexico (Plummer, Morrison, and Steiner 2012). To implement Gulf of Mexico (Plummer, Morrison, and Steiner 2012). Ti implement
the equimarginal principle, the marginal value-per-unit (i.e., pound) of landings is estimated for commercial and recreational sectors.
We use revealed preference (RP) recreation survey (intercept and telephone) data from NOAA for the South Atlantic and the Gulf of Mexico collected in 2003 and 2009 (Haab, et al. 2009) in conjunction with stated preference (SP) data collected in 2003 and 2009 (Wallmo and Gentner 2008). For RP analysis we use site -specific historic catch rates and expected catch rates (conditioning on anglers' characteristics) within common Random Utility Model (RUM) formulations to evaluate within common Random Utility Model (RUM) formulations to evaluate
factors influencing site choice, while mitigating onsite sampling biases factors influencing site choice, while mitigating onsite sampling biases
using weights (Hindsley, et al. 2011; Kuriyama, et al. 2013). The SP using weights (Hindsley, et al. 2011; Kuriyama, et al. 2013). The SP
analysis employs choice experiments to assess the influence of catch analysis employs choice experiments to assess the influence of catch
rates (and other factors) on site choice. The recreational analysis is rates (and other factors) on site choice. The recreational analysis is
tailored to permit joint estimation with RP and SP data. Lastly, multispecies profit functions are estimated using cost and earnings data for commercial fishers (Gentner 2012). Evaluation of the commercial sector includes analysis by gear type and fishing location, incorporating any fishery management plans relevant to the location or season.

## Methods

RECREATION: Random utility theory is the basis for recreational fishing models:

$$
\mathrm{U}_{\mathrm{ij}}=\mathrm{V}_{\mathrm{ij}}+\varepsilon_{\mathrm{ij}}
$$

where $U_{i j}$ is the utility angler $i$ receives from fishing alternative $j, i=1$,
$\ldots, I, j=1, \ldots, \mathrm{~J}, \mathrm{v}_{\mathrm{ij}}=\beta^{\prime} \mathrm{X}_{\mathrm{i}}$ is the systematic portion of utility, $\beta$ is a vector of parameters, $\mathrm{x}_{\mathrm{i}}$ is a vector of variables specific to choice, and $\varepsilon$ is the random error. Given the unobserved elements of utility, estimation is based on the probability of individual i choosing alternative j :

$$
\pi_{i j}=\operatorname{Pr}\left[V_{\mathrm{Vj}}+\varepsilon_{\mathrm{ij}} V_{\mathrm{ik}}+\varepsilon_{\mathrm{ik}}\right] ; \forall k \in \mathrm{~J} .
$$

The econometric specification depends upon the distribution of the error term and other elements of the choice model. Marginal values of recreational catch are calculated as MWTP $=\beta_{\text {catch }} / \beta_{\mathrm{tc}}$ and confidence intervals are generated by Krinksy-Robb. Combining RP and SP data permits additional variation in catch \& travel cost.

COMMERCIAL: A generalized Leontief dual revenue model is used for commercial analysis (Squires and Kirkley 1991).
$\pi(p ; K)=\sum_{i} \gamma_{i} p_{i} K^{2}+\sum_{i} \sum_{j} \phi_{i j}\left(p_{i} p_{j}\right)^{0.5} K+\sum_{i} \sum_{j} \mu_{i j} t_{j} p_{i}+\sum_{i} \sum_{j} \omega_{i j} i_{j} p_{i} K+\sum_{i} \sum_{j} \delta_{i j} c_{j} p_{i} K$
where $p$ are ex-vessel prices, $K$ is fixed capital, and $t, l$, and $c$ are dummy variables capturing time, location, and other control effects, respectively. From this specification, input-compensated supply equations can be derived for each species and the virtual prices for a pre-specified level of quota can be defined (Gentner 2012).

ALLOCATION: Recreational benefit: $\mathrm{B}=\mathrm{f}[\mathrm{q}, \mathrm{d}(\mathrm{q})]$ where q is catch per day and $\mathrm{d}(\mathrm{q})$ is the trip-response function for days fished. Allocation analysis employs this function to assess welfare change under binding quota constraints, bag limits, or site closures. Commercial benefits are simulated using the virtual price framework of Fulginiti and Perrin (1993).

## Results and Discussion

Recreation Values: RP estimates using VC of travel range from several dollars to under $\$ 10$, but increase $74-86 \%$ when using full cost travel; SP estimates using full cost are multiples of $\$ 10$ to well over $\$ 100$ Combined RP-SP model permits flexible scale parameter across respondents \& allows for random parameters, producing values between RP and SP (ranging from $\$ 4.50$ (Dolphin) to $\$ 48$ (King between RP and SP (ranging from $\$ 4.50$ (Dor to account for only VC Mackerel). These can be adjusted downward to account for only VC.
Commercial Values: Marginal profits calculated for 2016 allocations Commercial Values: Margina
range from $\$ 2$ to $\$ 4$ (2016\$)
range from $\$ 2$ to $\$ 4$ (2016\$)
Allocation Analysis: Economic efficiency may be enhanced through Allocation Analysis: Economic efficiency may be enhanced through analysis, however, requires analyzing changes in surplus from additional recreation catch and loss of producer surplus down the supply chain and reduced supply of seafood for consumption. This is the current focus of our project.

## Conclusions

We will consider behavioral responses in targeting and effort redirection in response to allocation changes through trip response models that utilize inclusive values from the RP-SP model as the dependent variable (Parsons, et al. 1999). Changes in days fished will be simulated by calculations of the inclusive value stemming from policy changes (i.e. recreational quota).

Lastly, consumer surplus of seafood consumers arising from seafood purchases in markets and restaurants will be estimated utilizing the synthetic inverse demand system (SIDS) model (Park, et al. 2004) as described in Gentner, et al. (2010, 2012). These techniques allow estimation of consumer demand functions from landings and ex-vessel value data available from NOAA. The methods support calculation of the marginal and non-marginal value (compensating variation) of commercial landings to seafood consumers.
