## IS THERE A DIFFERENCE? EXCHANGE RATE NONLINEARITIES IN EUROPEAN AGRI-FOOD (VERSUS TOTAL) EXPORTS TO THE US<sup>1</sup>

*Svetlana Fedoseeva*<sup>2</sup>

### Abstract

Each time the Euro starts appreciating, a discussion on how painful this might hit European exporters arises in media, making politicians and economists work out the ways to mitigate possible shocks. Still, in his recent study, VERHEYEN (2013a) showed, that in the long run exports react to exchange rate changes in a nonlinear and asymmetric way. Particularly his analysis revealed, that a positive impact on trade during the Euro depreciation seem to outweigh the losses caused by its appreciations. In this paper, I test whether this holds true for agri-food exports as well. To address this question, I apply a partial sum decomposition approach and the NARDL framework of SHIN et al. (2013) to aggregated agri-food exports as well as to total exports of eleven European countries to the US, which is currently the major partner of the EU in agri-food trade. The outcomes suggest, that exchange rate asymmetries are even more pronounced in agri-food than in total exports. Despite the ongoing discussion regarding the nocent effect of a strong national currency on exports, the estimation results suggest that European agri-food exporters have found their way to cope with such negative effects. European exporters seem to benefit more from Euro depreciation, than its appreciation harm them. I interpret this finding as a sign of pricing strategies application (e.g., pricing-to-market) to the European agri-food exports.

### Keywords

Agri-food exports, asymmetry, exchange rate pass-through, NARDL

### 1 Introduction

Although the investigation of trade determinants and trade elasticities has been playing an important role in international economic studies for many decades now, the question of possible nonlinearities in international trade stayed unaddressed till the end of 80s, when the sunk costs and hysteresis literature emerged (e.g., BALDWIN, 1990). According to hysteresis literature, nonlinearities in export demand might be driven by strategic behaviour of the exporters, who having once invested an amount of sunk costs into entering the market, try to gain or keep the market share in the destination country. Though these studies showed evidence in favour of nonlinearities, they were basically conducted using relatively simple methods, which did not allow to take time-series properties of data into account or to address nonlinearities and asymmetries of the underlying long-run relation between exports and exchange rates. The only exception from this pattern I am aware of is the study of VERHEYEN (2013a), who adopted a nonlinear autoregressive distributed lag approach (NARDL) of SHIN et al. (2011) to model nonlinearities not only in the short, but also in the long run in order to address the issue

---

<sup>1</sup> Work on this paper is based on the project “What Explains Agricultural Trade of the EU and Germany? Theoretical and Econometric Analyses on Liberalization, Macro Effects and Hysteresis” (HE 1419/12-1) financed by DFG. I am grateful to the organizers and participants of the INFER AC 2014 and WIEM-2014 for their valuable comments and intensive discussion. Remarks and suggestions of two anonymous reviewers are much appreciated.

<sup>2</sup> Justus-Liebig-Universität Gießen, Center for International Development and Environmental Research, Senckenbergstr. 3, 35390 Gießen; svetlana.fedoseeva@zeu.uni-giessen.de

of the exchange rate nonlinearities in the exports of twelve EMU countries to the US. That study focused on total exports, and nonlinearities in the export demand reactions to Euro appreciations and depreciations were found for many countries.

In this study, besides addressing total exports, I focus on agri-food exports. Excessive demand for EU agri-food products put European countries on the second position among the world top exporters. The US is the largest export market of the EU with an export share of 13 % in total agricultural exports (EUROPEAN COMMISSION, 2013). As around 80 percent of all agricultural EU exports are final goods (mainly spirits and liqueurs, wine and vermouth, beer, waters, dairy products, cereal, fruit and vegetable preparations and confectionery) I suppose to find a more pronounced evidence of exchange rate nonlinearities in the European agri-food exports than it was recorded for total exports. This is expected due to pricing-to-market strategies (as e.g. in KNETTER, 1989), which might be used by exporters in order to hinder the pass-through of Euro fluctuations to domestic US prices and to protect market shares. In total exports, the effect of pricing-to-market strategies might be hindered by a higher aggregation of data.

To test whether exchange rate nonlinearities are indeed more pronounced in agri-food trade, I analyse agricultural exports of eleven European countries to the US over the last 25 years. As my model specification is somewhat different from the existing studies (with regard to definition of variables, choice of thresholds, etc.), I also re-estimate the export demand equations for total exports. This is done in order to compare the outcomes with the only empirical study available (VERHEYEN, 2013a) and to check whether results are robust to different model specifications and to have a reference for conclusions regarding nonlinearities in agri-food exports. In order to allow for nonlinearities in the short and in the long run and to address the time-series properties of data (possible hidden cointegration) I apply the partial sum decomposition combined with the NARDL approach of SHIN et al. (2013) and the bounds testing approach by PESARAN et al. (2001).

The remainder of the paper is structured as follows: Section 2 describes the methodology, Section 3 introduces the data, Section 4 presents the results and the last section provides a brief summary.

## 2 Methodology

Let us assume that the European exports to the US can be described by a reduces-form equation<sup>3</sup>, which can be written, depending on the way of including of the real exchange rate in it, as:

$$(1) X_t = A * R_t^\alpha * Y_t^\beta, \text{ or}$$

$$(2) X_t = B * E_t^\gamma * P_t^\delta * Y_t^\zeta,$$

where the European exports to the US at time  $t$  ( $X_t$ ) are determined by some constant parameter ( $A$  or  $B$ ), the US demand  $Y$ , and the real exchange rate ( $R$ ), which is included in the second specification as a nominal exchange rate ( $E$ ) and a relative price ( $P$ ), in order to separate the exchange rate and the price effect. The exponents refer to the elasticities of exports with respect to the foreign demand and the real exchange rate (or to the nominal exchange rate and the relative price in the second case).

Taking logs of Equations 1 and 2 results in following Equations 3 and 4, which represent long-run relationships between exports and their determinants (the lower case letters denote logs):

$$(3) x_t = a + \alpha r_t + \beta y_t$$

$$(4) x_t = b + \gamma e_t + \delta p_t + \zeta y_t.$$

---

<sup>3</sup> Similar demand functions were specified in e.g. BAHMANI-OSKOOEE and KARA (2003) or VERHEYEN (2013b).

To address nonlinearity of the US export demand with respect to the exchange rate, I apply the partial sum decomposition approach by SHIN et al. (2013). Here I stick to a two-threshold decomposition case, which let me not only distinguish between appreciations and depreciations of the exchange rate, but also to separate small from large exchange rate changes, as it was often suggested empirically that exporters behaviour might be a subject to hysteresis and the exporter might not react the same way on exchange rate changes of different magnitudes (e.g., BALDWIN, 1988; BELKE et al., 2013). The exchange rate decomposition takes the following form for the real exchange rate:

$$(5) r_t = r_0 + r_t^- + r_t^\pm + r_t^+,$$

and analogously for the nominal exchange rate:

$$(6) e_t = e_0 + e_t^- + e_t^\pm + e_t^+.$$

Unlike VERHEYEN (2013a) I decompose not the original series, but the log of the exchange rate here, which allows me to avoid problems related to taking logs of negative numbers (exchange rate depreciations) and to interpret exchange rate coefficients as elasticities. Instead of using various quantiles I fix thresholds at the level of one positive and negative standard deviation, as it lets me show how the export reaction changes within the range of standard fluctuations of exchange rates and outside of it. The real exchange rate series is decomposed as:

$$(7) r_t^- = \sum_{j=1}^t \Delta r_j^- = \sum_{j=1}^t \Delta r_j I\{\Delta r_j \leq -STD\};$$

$$(8) r_t^\pm = \sum_{j=1}^t \Delta r_j^\pm = \sum_{j=1}^t \Delta r_j I\{-STD < \Delta r_j < +STD\};$$

$$(9) r_t^+ = \sum_{j=1}^t \Delta r_j^+ = \sum_{j=1}^t \Delta r_j I\{+STD \leq \Delta r_j\}.$$

The decomposition of the nominal exchange rate is done analogously. Then the export Equations 3-4 take the following form:

$$(10) x_t = a + \alpha_1 r_t^- + \alpha_2 r_t^\pm + \alpha_3 r_t^+ + \beta y_t,$$

$$(11) x_t = b + \gamma_1 e_t^- + \gamma_2 e_t^\pm + \gamma_3 e_t^+ + \delta p_t + \zeta y_t.$$

In this representation I still have (the log of) original exchange rate series, which is now substituted by three partial sums. This allows me to test the long-run relation between the positive, negative and small changes of the exchange rate and the export demand in the long run. The only observation that I lose due to such an exchange rate decomposition will be captured by the constant. The same holds true for the nominal exchange rate partial sum decomposition.

As I deal with variables, which are often nonstationary, such long-run representation might be spurious, once time-series properties of data are not taken into account. On the other hand, all the standard methods of a unit-root and cointegration testing might be not applicable, as the original variable is decomposed. Using NARDL allows me to take into account the possible hidden cointegration between positive and negative components of underlying variables (GRANGER and YOON, 2002) and test for a presence of a long-run relationship between the level variables irrespective of their order of integration (I(0), I(1) or mixed) by means of a bound testing approach by PESARAN et al. (2001)<sup>4</sup>.

The NARDL model for the export demand Equation (10) can be written as:

$$(12) \Delta x_t = a_0 + a_1(x_{t-1} - a_2 r_{t-1}^- - a_3 r_{t-1}^\pm - a_4 r_{t-1}^+ - a_5 y_{t-1}) + \sum_{\tau=0} \eta_\tau \Delta r_{t-\tau}^- + \sum_{\tau=0} \theta_\tau \Delta r_{t-\tau}^\pm + \sum_{\tau=0} \iota_\tau \Delta r_{t-\tau}^+ + \sum_{\tau=0} \kappa_\tau \Delta y_{t-\tau} + \sum_{\omega=1} \lambda_\omega \Delta x_{t-\omega} + u_t$$

The NARDL representation of the model with nominal exchange rate is constructed analogously:

<sup>4</sup> There are no variables integrated of order two in my sample.

$$(13) \Delta x_t = b_0 + b_1(x_{t-1} - b_2e_{t-1}^- - b_3e_{t-1}^\pm - b_4e_{t-1}^+ - b_5y_{t-1} - b_6p_{t-1}) + \sum_{\tau=0} \mu_\tau \Delta e_{t-\tau}^- + \sum_{\tau=0} \nu_\tau \Delta e_{t-\tau}^\pm + \sum_{\tau=0} \xi_\tau \Delta e_{t-\tau}^+ + \sum_{\tau=0} \sigma_\tau \Delta y_{t-\tau} + \sum_{\tau=0} \pi_\tau \Delta p_{t-\tau} + \sum_{\omega=1} \rho_\omega \Delta x_{t-\omega} + u_t$$

The appropriate lag structure is chosen according to the Schwarz criterion. When the autocorrelation is still present in the suggested specification, I add the lags of the first difference of the dependent variable in order to overcome the problem. In any case, a maximum lag length of 12 is considered as monthly data is used.

As the estimation of NARDL with ordinary least squares (OLS) delivers only a product of the exchange rate coefficient and the coefficient of the lagged export demand, I recalculate the long-run elasticities as follows:

$$(14) \text{rer}^- = -\frac{a_2}{a_1}; \text{rer}^\pm = -\frac{a_3}{a_1}; \text{rer}^+ = -\frac{a_4}{a_1};$$

$$(15) \text{er}^- = -\frac{b_2}{b_1}; \text{er}^\pm = -\frac{b_3}{b_1}; \text{er}^+ = -\frac{b_4}{b_1}.$$

The standard errors and significance levels of the recalculated long-run elasticities are obtained using the Delta method. To test for a long-run level relationship between level variables, I conduct the Bounds testing by PESARAN et al. (2001). This is done by testing the  $H_0$  of  $a_1 = a_2 = a_3 = a_4 = a_5 = 0$  in the Equation 12 and the  $H_0$  of  $b_1 = b_2 = b_3 = b_4 = b_5 = b_6 = 0$  in the Equation 13 and comparing the test statistics with the critical values tabulated by PESARAN et al. (2001).

The symmetry is tested by means of a Wald test. Rejection of the  $H_0$  of symmetry suggests a nonlinear export demand reaction towards appreciations and depreciations. As there might be not much variation within the inner regime I suppose to face some certain difficulties in proving hysteresis in the sense of VERHEYEN (2013a), who stated that hysteresis can be indicated by a stronger reaction to large than to small exchange rate changes. Still, I suppose to see non-linearity in the response of the export demand to exchange rate changes of different magnitudes. Furthermore, positive values for the estimates of the foreign demand ( $y$ ) and negative coefficients at the relative prices ( $p$ ) are expected. As exports and exchange rates are typically inversely related, I also await negative signs at the exchange rate coefficients.

### 3 Data

My export data are taken from the Eurostat and consist of bilateral nominal total and agricultural exports from 11 EMU countries to the US measured in Euro. The sample includes monthly data from January 1988 to August 2013. For two countries in the sample (Austria and Finland), the export series are only available from January 1995 on. For aggregated exports, I use total exports according to the Standard International Trade Classification (SITC) classification. The analysed agricultural exports are limited to SITC group 0 “Food and live animals”, which includes, e.g. meat and preparations, dairy products, cereals and preparations, fruits and vegetables, coffee, sugar and confectionery. In order to deseasonalise nominal exports I apply the Census-12 procedure. Relative prices are calculated as consumer price index (CPI) of a corresponding European country divided by the US CPI series. The US demand is approximated by the index of industrial production (IIP), as it is available on a monthly basis. The IIP and the CPI are collected from the OECD Main Economic Indicators database and are already seasonally adjusted.

Nominal exchange rates are measured as units of the American Dollar (USD) per 1 Euro and are taken from Eurostat. In order to adjust the exchange rates for the period before the introduction of the Euro, I use the official conversion rates to calculate the bilateral exchange rate series. In order to obtain real exchange rates, bilateral nominal exchange rate series are multiplied by relative price measures. Thus, an increase in the exchange rate corresponds to a Euro appreciation. Partial sums are calculated as described in the Methodology Section.

The US is one of the most relevant trade partners of the European countries and the main importer of European agricultural products in recent years. For many EMU countries, the US is the major export destination outside of the Eurozone (VERHEYEN, 2013a). Figure 1 provides some overview of the relevance of the US market for the exports of the considered European countries.

**Figure 1: Exports to the US relative to all country's exports (average of 1988-2012, %)**

Source: Own representation, based on data from EUROSTAT (1988-2012)

## 4 Results

In this section, I proceed with the outcomes of the estimated models. As nonlinearities in export reactions to exchange rate changes were mostly neglected in empirical literature, I compare the outcomes for total exports with those of VERHEYEN (2013a), and then collate these results with the outcomes received for agri-food exports to see whether some differences/similarities can be found there.

### 4.1 Total exports

The outcomes obtained for total exports<sup>5</sup> are very much in line with those of VERHEYEN (2013a), despite the fact that my sample is somewhat larger, the exchange rates enter the equations in logs and the threshold levels are not similar. The chosen lag structure and the explanatory power of the models are also compatible in most of the cases. The average adjusted coefficient of determination in my sample takes the value of 0.391, ranging from 0.286 to 0.529 across the models.

The evidence in favour of a long-run level relationship is quite strong. The only models for which I could not reject the  $H_0$  of no cointegration were the ones for Austria, Netherlands and Ireland (only for the model with a nominal exchange rate). Estimated coefficients carry mostly expected signs and show that the US income approximated by the industrial production

<sup>5</sup> The outcomes of the estimated NARDL models for total exports as well as for agri-food exports are skipped here in order to save space. Still the quality of estimated models is discussed to validate presented long-run coefficients. Complete results are available upon request.

index, positively and over proportionally affects European exports to the US, while inflation has a negative impact.

Table 1 reports recalculated long-run export demand elasticities with respect to exchange rates. The outcomes suggest that exchange rates do affect European exports. The values of coefficients of nominal and real exchange rates are quite close in absolute terms and are mostly significant. For most of the models, irrespective of the specification, coefficients related to Euro depreciations are larger in absolute terms than those related to Euro appreciations. This supports the idea, that the EU countries benefit more from the Euro depreciations than they suffer from the reduction in the US export demand, once the Euro appreciates. As for hysteresis, I was not able to find any robust evidence in favour of it, apart from France, Greece, Italy and Spain, for which the coefficients at the inner regime of exchange rate are smaller in absolute terms, than those at large appreciations and depreciations.

Table 2 provides an overview of a symmetry testing. Symmetry between all the exchange rate coefficients is rejected for seven (eight) out of eleven cases for the models with real (nominal) exchange rates as explanatory variables. The most pronounced and robust evidence in favor of nonlinearities is found for Austria and Belgium, where the hypothesis of equality of long-run coefficients of the exchange rates is rejected for both models and for all of the exchange rate coefficients' combinations. Symmetry between the two outer regimes – appreciations and depreciations – was rejected for all the countries but Finland<sup>6</sup>, France and Ireland, for which I conclude, that the magnitude of the reaction of the exports does not depend on direction of exchange rate changes.

## 4.2 Agri-food exports

The overall fit of the models, which focus on the US export demand for agri-food products, is somewhat higher than for total exports. Adjusted R-squared takes the value of around 0.405 on average, with the values on a country level ranging from 0.291 to 0.471. The evidence in favour of cointegration in equations for agri-food exports is even more pronounced than in the models with total exports as dependent variable. The bound testing suggests that there is a long-run relationship between level variables in all models.

Most of the coefficients of the estimated NARDL models have expected signs. The export demand for food products, when significant, mostly enters equations with a positive sign. Similarly to the case of total exports, the nominal exchange rate itself seems to be more important than inflation, as the coefficients of nominal and real exchange rates in different model specifications do not differ much. For agri-food exports, the exchange rate seems also to be more important than the US income: while only half of the industrial production indices are statistically significant, exchange rate coefficients (especially the ones capturing depreciations) are often of high statistical significance. The only exclusion is Austria. Finland, France, Greece, the Netherlands, Portugal and Spain seem to benefit the most from the Euro depreciations. In the meantime, those are in general also the countries who suffer the most from Euro appreciations. Still, Euro appreciations do not seem to harm the export demand much. The coefficients for Euro depreciations are often considerably higher in absolute terms than the ones for appreciations. Table 3 reports long-run elasticities of food exports with respect to exchange rate changes.

There might be some plausible reasons for such asymmetric reactions of exports: as European countries export a lot of processed goods to the US, some of those products might have gained certain reputation on the American market. If that is the case, the US consumers do not

---

<sup>6</sup> The outcomes for Finland should be treated with caution. The equation seem to be misspecified, as the speed of adjustment is higher than one in absolute terms, which implies some overshooting. This might be due to a shorter time span, as in case of Finland, the data is only available from 1995, and a poorer performance of NARDL in short samples.

switch away from European goods as their local prices in US Dollars rise, and consume more, once the Dollar price falls. It could also be the case that European food exporters, who perceive the US market as strategically important, apply some pricing strategies (e.g., pricing-to-market) in order to partially offset the currency volatility and smooth fluctuations in shipped quantities, by reducing markups they set on marginal costs. Then total agri-food imports of European products by the US do not change much, as Euro appreciates. (Asymmetric) strategic pricing might be a plausible explanation behind the nonlinearity and asymmetry of export volumes' reactions towards Euro appreciations and depreciations, as empirical literature often found evidence of pricing-to-market of European exporters, especially in their trade with the US (e.g., KNETTER 1989, 1997; FALK and FALK, 2000; GLAUBEN and LOY, 2003; STAHN, 2007).

The evidence in favour of hysteresis is also more pronounced for agri-food than for total exports, which supports the sunk costs hypothesis. For agri-food exports hysteresis is found for Belgium, France, Greece, Italy, Portugal and Spain.

Table 4 provides the outcomes of the symmetry testing for the food export demand. The equality of all the long-run exchange rate coefficients is rejected in ten out of eleven cases in both model specifications. Thus, Ireland is the only country, for which the symmetry of the export's reaction on exchange rate changes of different direction and magnitude could not be rejected. In general, asymmetry between the appreciations and depreciations is more pronounced, than between those and the inner regime. The evidence in favour of nonlinearities is larger for food export equations compared to equations with total exports as dependent variable. This suggests that assuming linearity and symmetry in export demand functions, as it has been often done in the literature, might well lack a rationale, once one assumes imperfectly competitive segmented markets.

## 5 Summary

In this paper I concentrated on the relationship between the agri-food exports and exchange rates and tested if this relationship is linear, using the newly developed methodology of SHIN et al. (2013), which allowed me to model exchange rate nonlinearities in export demand equations not only in the short, but also in the long run. Furthermore, I compared the outcomes for agri-food products with results for aggregated total exports, and showed that assuming linearity of the export's reaction to exchange rate changes is very restrictive in both cases.

Results of the analysis, which was carried out using monthly data on nominal exports from eleven European countries to the US during 1988-2013, showed, that exports react differently on appreciations and depreciations of the Euro. The same holds true for small and large exchange rate changes. Even though the outcomes differ a lot between countries<sup>7</sup>, they suggest that European exports benefit more from Euro depreciations, than the Euro appreciations harm them. This result is even more pronounced when agri-food exports are considered. I was able to reject the symmetry hypotheses between all the exchange rates regimes in 91 percent of cases for agricultural exports and found support in favour of hysteresis in half of the cases.

As European countries export a lot of final goods to the US, which is their most important trade partner outside of the Eurozone, it seems like European exporters apply pricing-to-market strategies in order to stay competitive on the US market and protect their market shares by partially offsetting Euro appreciations. Euro depreciations might be used in order to gain competitiveness and expand exports. Numerous empirical pricing-to-market studies support this hypothesis for the case of agri-food exports, chemical products and manufactured goods, especially vehicles. The outcomes obtained for agri-food exports suggest that pricing-to-market might play an important role in European exporters' trade decisions (and that pric-

---

<sup>7</sup> This might well be due to a difference in the composition of exports across exporting countries or a whole lot of other related factors. Data that is more detailed is required to formally test this hypothesis.

ing-to-market might be well asymmetric as well). The outcomes obtained for total exports might then reflect a higher degree of aggregation, as heterogeneous final goods, for which pricing-to-market strategies in export pricing are expected, and homogeneous commodities, which are often traded at world prices, are mixed together. As shares of different products in the structure of total exports are unknown, one cannot distinguish between the export demand reactions to the exchange rate changes within different groups of goods, which would require more disaggregated data. Additionally, in order to better explain the cross-countries differences, one should focus on a more disaggregated agri-food product groups (e.g. milk and milk products, fruits and vegetables and their preparations). As European markets are highly integrated, one might also think of nesting the NARDL approach into a panel setting in order to address possible third-country effects<sup>8</sup>. As implementing these ideas requires an independent large-scale study, at this point these suggestions are left for future research.

---

<sup>8</sup> I am thankful to two anonymous referees at the 54th Gewisola-Tagung for these last two comments.
