Impact Evaluation of the Feed the Future Cambodia Helping Address Rural Vulnerabilities and Ecosystem Stability (HARVEST) Project

by

Mywish K. Maredia, Murari Suvedi, Raul Pitoro, and Raju Ghimire
The Michigan State University (MSU) International Development Paper series is designed to further the comparative analysis of international development activities in Africa, Latin America, Asia, and the Near East. The papers report research findings on historical, as well as contemporary, international development problems. The series includes papers on a wide range of topics, such as alternative rural development strategies; nonfarm employment and small-scale industry; housing and construction; farming and marketing systems; food and nutrition policy analysis; economics of rice production in West Africa; technological change, employment, and income distribution; computer techniques for farm and marketing surveys; farming systems and food security research.

The papers are aimed at teachers, researchers, policy makers, donor agencies, and international development practitioners. Selected papers will be translated into French, Spanish, or other languages.

Copies of all MSU International Development Papers, Working Papers, and Policy Syntheses are freely downloadable in pdf format from the following Web sites:

August 2017

Maredia is Professor, International Development and Pitoro is Research Associate, Department of Agricultural, Food, and Resource Economics; Suvedi is Professor and Ghimire is Research Scholar, Department of Community Sustainability, Michigan State University, East Lansing, Michigan, USA.
ACKNOWLEDGMENTS

This study is made possible by the generous support of the American people through the United States Agency for International Development (USAID) with funding through the Food Security III Cooperative Agreement No. GDG-A-00-02-00021-00 and Associate Award No. AID-442-LA-12-00001. The contents are the responsibility of the authors and do not necessarily reflect the views of USAID, the United States government or Michigan State University.

The authors would like to thank several organizations and individuals without whom this undertaking would not have been possible. First and foremost, thanks to USAID/Cambodia for providing essential funding and resources in support of this evaluation project. The cooperation and support from USAID Food Security and Environment Program directors, agriculture officers, dedicated evaluation specialists, and support staff at USAID/Cambodia were instrumental to the implementation and completion of this project.

Several members of the Michigan State University (MSU) faculty have contributed to this evaluation. Dr. Rui Benfica extended technical assistance during the baseline study. Dr. Duncan Boughton, Dr. Kimberly Chung, Dr. Michael Kaplowitz and Dr. Robert Richardson provided invaluable support during the various phases of this evaluation. Socheat Keo, graduate student in the Department of Community Sustainability (CSUS), helped with his translation skills and by responding to queries that required local knowledge. We would also like to thank Sreng Bora for his assistance in training enumerators and providing supervision during the fieldwork. We are also grateful to Dr. Ahsanuzzaman, assistant professor at North South University, Bangladesh, for his guidance on identification strategies and the use of various econometrics techniques.

Baseline information was collected during August-October, 2012, by the Cambodia Development Resource Institute (CDRI) through funding from the Cambodia HARVEST project with technical guidelines from Michigan State University. We are grateful to Dr. Theng Vuthy for his leadership in the baseline survey. Endline data was collected during August-September 2016 by the CDRI with a subcontract from Michigan State University and technical support from the MSU team. We acknowledge the contribution of CDRI under the leadership of Sim Sokcheng for timely completion of the endline survey data collection.

We would also like to thank the enumerators, supervisors, and thousands of farmers who participated in the baseline and endline surveys. Without their time, efforts and hard work, this evaluation would not have been possible.

We acknowledge the support we received from all these individuals and extend our gratitude to all those who guided us and participated in the study. Lastly, we thank the reviewers for their feedback on earlier versions of this report and suggestions for improvement and Patricia Johannes for her careful and detailed formatting assistance. All errors remain the responsibility of the authors.
EXECUTIVE SUMMARY

The Cambodia Helping Address Rural Vulnerabilities and Ecosystem Stability (Cambodia HARVEST) was a five-year (December 2010-June 2016) USAID Feed the Future (FTF) initiative implemented in selected districts across four provinces of Cambodia – Battambang, Pursat, Siem Reap, and Kampong Thom. HARVEST program interventions focused on increasing incomes to influence nutrition outcomes. This was achieved through an approach that integrated activities from a range of sectors—agriculture, fisheries, forestry, nutrition and more—to help families in rural areas grow, purchase, and prepare more nutritious foods. Cambodia HARVEST was rolled out in phases over the 5 1/2-year period, which ended in June 2016. Over that time, the project’s strategy evolved as activities were scaled up, but the overall approach remained guided by the principles of linking agriculture and nutrition to achieve some of the overarching development goals of reducing poverty and malnutrition.

To assess whether this approach of linking agriculture and nutrition through a comprehensive development project such as Cambodia HARVEST is effective, USAID/Cambodia funded Michigan State University (MSU) to conduct an independent and rigorous impact evaluation of the Cambodia HARVEST as part of its overall FTF monitoring and evaluation strategy. To this effect, baseline and endline data were collected in 2012 and 2016, respectively. This report presents the results of the endline survey conducted in HARVEST targeted villages to assess whether and by how much project outcome status of some key FTF indicators along the impact pathway improved for Cambodia HARVEST clients compared with the baseline. It also presents the results of the impact evaluation of project interventions using rigorous methodologies that take into account counterfactuals and selection bias issues to assess whether the observed changes in outcome status of client households can be attributed to Cambodia HARVEST.

Evaluation Design, Data, and Methodology

The request to design an impact evaluation of Cambodia HARVEST was made to MSU after the project had already selected and initiated interventions in some villages but before it identified all the project villages and beneficiaries to be targeted over the five-year period. This obviated an impact evaluation strategy based on a randomized controlled trial. The only rigorous method that was available to address the program placement bias and farmer self-selection bias to assess causal effects was the difference-in-difference (DiD) approach combined with propensity score matching (PSM), which we used for this evaluation. This quasi-experimental Sample involved collecting baseline and endline data from a sample of farmers from villages designated as the treatment group, and from villages designated as the comparison group. The propensity score matching method was applied to the baseline data first to create treatment and comparison groups that match on propensity score. This was followed by estimating the average effect of HARVEST interventions across all the sampled households that had received direct technical assistance from Cambodia HARVEST compared with the effects across all the sampled households in the comparison villages.

Baseline data were collected in 2012 from 1,500 farm households representing 60 Cambodia HARVEST villages and 600 households representing 24 comparison villages that were projected not to receive any Cambodia HARVEST intervention. The average distance between the comparison village and the nearest treatment village included in the sample was about 4 km. In 2016, the same 2,100 households were revisited to complete an endline survey. However, there was an attrition of 179 households, which reduced the total number of reinterviewed households from 2,100 to 1921. The 1,500 treatment households surveyed in
2012 were selected from a list of households provided by Cambodia HARVEST that were targeted to receive interventions in 2012 or 2013. However, 127 households resurveyed in 2016 were found to have not participated as clients, and another 185 did not graduate from the program as planned. To evaluate the effects that the project had on the client beneficiaries, we use only those households that actually participated in Cambodia HARVEST as clients. We thus use two analytical samples to estimate the program effects. Sample 1 includes only client households that were active or had graduated from Cambodia HARVEST and are considered the true treatment sample (1,088 households). Sample 2 includes all client households, irrespective of whether they graduated or dropped out of the program (1,273 households). PSM-DiD estimates based on sample 1 measure the average treatment effect on the treated (ATT), and those based on sample 2 measure the intent to treat (ITT) effects.

**Descriptive Analysis Results**

The 2016 survey data indicate that about 60% of households in both the treatment and comparison groups had participated in at least one activity/intervention organized by government or other NGOs in the previous four years. This reflects potential contamination of project interventions in comparison villages that could bias the results of impact evaluation.

The descriptive analysis points to the project’s success in influencing the general awareness and knowledge about concepts, terminologies, and practices promoted by the project. The women in the treatment group also reported having a higher level of knowledge about some of the food consumption practices for children and adults, the concept of three food groups, and practices related to good hygiene than women in the comparison group.

Beyond awareness and knowledge, the respondents in Cambodia HARVEST intervention villages also reported a high prevalence of uptake and adoption of good agricultural production and nutrition practices promoted by the project. Also, a significantly higher percentage of farmers in treatment villages than farmers in comparison villages reported having adopted some of the improved technologies and practices promoted by the project for rice, such as direct sowing of rice, row planting, and short-duration rice varieties, and for vegetables, such as raised planting beds, the use of mulch, drip irrigation, trellis netting, and nurseries. A significantly higher percentage of treatment farmers reported having tried a wide range of new techniques for both rice and vegetables over the previous four years. However, consistent with evidence elsewhere there remains a substantial gap between awareness and uptake, and between uptake and current adoption of improved technologies. For instance, only 50% of farmers who become aware of a new technology had tried it or taken it up, and only 50% of those that had tried it continued to use the technology when interviewed in 2016. Beyond adoption and uptake of improved practices, the results of descriptive analysis also indicate that, on indicators of productivity, crop income, expenditures, poverty, hunger, dietary diversity, and indicators of malnutrition, sampled households from the Cambodia HARVEST-targeted villages saw a significant improvement from the levels observed in 2012 (start of the project) to 2016 (end of the project). For example, among the villages targeted for Cambodia HARVEST interventions, the poverty rate significantly decreased from 12% to 4% during that four-year period. Annual per capita expenditure on food and non-food items (excluding housing) increased from US$547 in 2012 to US$609 in 2016 among treatment households. The prevalence of stunting, wasting, and underweight among children younger than 5 was, respectively, in the range of 30%, 10%, and 20% among the treatment group in 2016, which was a reduction from the observed rates (i.e., 45%, 10%, and 30%, respectively)
in 2012. A key finding of this study is that similar improvements in these indicators were also observed in non-treatment villages. The fact that there were other donor and government programs active in the comparison villages could be a plausible explanation of this outcome.

**Results of Impact Analysis**

We present results of impact analyses based on the PSM-DiD approach using two analytical samples to estimate the average treatment effect on the treated (sample 1) and the intent to treat treatment effect (sample 2). For further robustness check, we estimated the program effect using both correlated random effects and household fixed effect models.

The analysis failed to detect statistically significant and robust impacts of Cambodia HARVEST. In other words, comparing the before and after intervention data between the treatment and comparison villages and controlling for potential confounding factors show no statistically significant effect of the program in changing the average values of these key indicators.

The only indicators for which the program shows a significant effect in one of the models—are the prevalence of wasting and underweight among children younger than 5 years, and rice yield per household. Results of the correlated random effect (CRE) model indicate the program contributed about 9% reduction in wasted children (in both sample 1 and sample 2). On the other hand, the program effect is opposite for underweight children. It is estimated that the program increased underweight children by about 9% (only in sample 2). Both these positive and negative effects on child nutrition observed under CRE model are not sustained, however, when we used the household fixed effects model. For rice, the results indicate 0.12 t/ha reduction in yield for sample 2, but only in the FE model. Most of these negative effects are associated with male-headed households (-0.17 t/ha) and in Pursat Province (-0.30 t/ha). In terms of differential program effects by gender or location, there are few statistically significant robust effects. One such effect of the HARVEST program is the positive effect of increasing the value of vegetable production for female-headed households by 0.16 million Riels.

The Report discusses several potential reasons for the overall inconclusive results of the impact analysis, including: 1) the reduced sample size which lowered the statistical power to detect treatment effects; 2) non-conformity of treatment households, which lowered the intensity of treatment and significantly reduced the sample size of the treatment group; 3) contamination of control group from the presence of other similar programs and potential spillover effects of Cambodia HARVEST; 4) the service delivery approach taken by Cambodia HARVEST that included intensive technical assistance to clients for 18-24 months, but no contact with extension service providers after that to reinforce the messages and techniques extended by the project; and 5) the possibility the impacts are still not realized and this evaluation may have taken place too soon.

**Conclusions**

The main findings of this study are that, on all counts of productivity, crop income, expenditures, poverty, hunger, dietary diversity and indicators of malnutrition, Cambodia HARVEST client households saw a significant improvement from the levels observed in 2012 (baseline) to 2016 (endline). The non-project beneficiaries also saw similar levels of improvements, however, perhaps due to the presence of other donor and government programs or because of spillover effects of Cambodia HARVEST due to the close proximity
of treatment and comparison villages. The PSM-DiD-based impact analysis thus failed to
detect any statistically significant program effect on the treated or intended to treat
households. Because of these confounding factors—i.e., presence of other donors and
government programs in the study area, and potential contamination from close proximity of
treatment and comparison villages—this study cannot arrive at any conclusions about the
relative effectiveness of Cambodia HARVEST, other donor programs, or no interventions.

Rigorous impact evaluation can yield strong evidence of the causal effects of a program. But
this method is not practical in all settings. We hope that the issues and challenges identified
in this study will provide some guidance on the appropriateness of rigorous impact
evaluations of such large-scale comprehensive development projects in future.

1. INTRODUCTION

The U.S. government launched its presidential Feed the Future (FTF) initiative in 2010 with the goal to reduce hunger, poverty, and malnutrition taking into consideration three cross-cutting issues: gender equity, environment, and climate change. The core investment areas of the initiative are women’s empowerment, diet quality and diversification, agricultural productivity growth, postharvest infrastructure, high-quality inputs, and financial services. The high-level target of the initiative is to reduce the prevalence of extreme poverty (those living on less than U.S. dollars (US$) 1.25 per day) and the prevalence of stunting among children under age 5 by 20% across all FTF focus countries over the five years in targeted geographic areas known as the zones of influence (ZOI).

Cambodia was designated as one of the focus countries under the Feed the Future Initiative. The development hypothesis guiding the FTF-Cambodia strategy rests on the benefits of diversification for managing risks faced by farmers and the extreme poor of Cambodia. Diversifying both agricultural production and sources and timing of income for rural households helps reduce hunger and poverty (USAID 2009: Cambodia FTF Strategy 2011-2015). The Royal Government of Cambodia’s development strategy to promote the growth of the agricultural sector and increase food security, environmental sustainability, and climate change resilience closely aligns with the FTF initiative.

The FTF-Cambodia program is implemented via multiple projects, of which Cambodia HARVEST (Helping Address Rural Vulnerabilities and Ecosystem Stability), implemented from December 2010 to June 2016, was the largest. Cambodia HARVEST aimed to increase incomes and improve food security for 70,000 rural Cambodian households across four provinces around Tonle Sap Lake: Battambang, Pursat, Siem Reap, and Kampong Thom. At the end of the project in 2016, HARVEST had reached over 100,000 households in the four target provinces (Fintrac 2016a). The project had developed and disseminated solutions for a variety of development challenges, including low agricultural productivity, high postharvest losses, lack of food safety regulations, constrained market access, and environmental degradation. Furthermore, the program trained over 71,400 people on nutrition and good eating practices to reduce stunting and wasting (Social Impact 2015).

Similar to the overall FTF strategy, the Cambodia HARVEST interventions were guided by the principles of linking agriculture and nutrition to achieve some of the overarching development goals related to poverty and malnutrition (FAO 2013). Over time, Cambodia HARVEST interventions focused on increasing incomes to influence nutrition outcomes. This was achieved through an approach that integrated activities from a range of sectors—agriculture, fisheries, forestry, nutrition, and more—and built the capacity of governments, local communities, and health workers to help families in rural areas grow, purchase and prepare more nutritious foods.

To assess whether this approach of increasing farmers’ incomes by focusing on specific value chains and linking agriculture and nutrition through a comprehensive development project such as Cambodia HARVEST is effective, and to guide future program investments, USAID/Cambodia USAID/Cambodia funded Michigan State University in 2012 to conduct an independent impact evaluation of the HARVEST project using rigorous methods as part of

---

2 Individual country-level targets are set against these goals and based on the conditions and context on the ground, and range between 15% and 30% in each country, averaging approximately 20% overall (see FTF M&E Guidance Series Volume 9.1: Target Setting for Reducing the Prevalence of Poverty, 2013).
its overall FTF monitoring and evaluation strategy. The distinctive feature of an impact evaluation (as opposed to a performance evaluation) is the use of a counterfactual, which identifies what would have happened to the beneficiaries in the absence of the program. This counterfactual is critical to understanding the improvements in people’s lives that are directly caused by the program. An impact evaluation was deemed important because of the large amount of resources being invested by USAID in the HARVEST project and the large number of people targeted by the project. Also, at that time, Cambodia HARVEST was one of the first FTF programs based on the principle of linking agriculture to nutrition, and in general, little was known about the effects of this new approach promoted under FTF. These efforts reflected USAID/Cambodia’s commitment to conducting a rigorous and independent impact evaluation of its flagship program as an integral part of the overall focus on results-driven planning and performance-based management. In general, impact evaluations aim to measure the changes in individual, household or community well-being that result from a particular project or program (in this case Cambodia HARVEST).

The HARVEST project was rolled out in phases over the 5 1/2-year period, which ended in June 2016. The Cambodia Development Resource Institute (CDRI) was sub-contracted to conduct the baseline survey (with technical input from MSU) during August-October 2012 (Vuthy et al. 2013). The purpose of this study is to report the results of the endline survey conducted in August-September 2016 and the results of the impact evaluation to measure whether the project had a discernible impact on its beneficiary population with respect to the FTF high-level goals and some key indicators. This impact evaluation analyzes the effect of Cambodia HARVEST’s exposure as well as the effect of FTF-type development interventions in the target areas on a subset of villages and client farm households that represented early cohorts of project beneficiaries. The early cohorts of project beneficiaries mostly received Cambodia HARVEST interventions on home gardening, rice, and aquaculture value chains in 2012, 2013, and 2014, but some households were also receiving Cambodia HARVEST interventions until 2015. The impact analysis is based on the baseline and endline data collected in 2012 and 2016 (in the same timeframe), respectively, for this early cohort of villages that were selected in 2012.

The report is organized as follows. In the first two sections, we present the context and background for this evaluation, including the development challenges and the scope and geographic focus of the Cambodia HARVEST. The conceptual framework underlying the descriptive and impact analyses of this study is discussed in Section 3, followed by the description of data and methodology. We present the results of the descriptive analysis by tracking the project inputs, outputs and outcomes along the impact pathway, and the results of the regression analysis to assess the program effects on selected FTF indicators. The last section concludes with discussions based on the overall results, limitations of the study, and emerging lessons and proposed next steps.
2. CONTEXT AND BACKGROUND

2.1. Development Challenges in Cambodia

Cambodia is home to more than 15 million people. It is a predominantly rural society with more than 70% of the population relying on agriculture for their livelihoods. Food production, food availability, and health indicators have improved steadily in the past decade, but challenges remain, including a relatively high incidence of rural poverty and malnutrition. For instance, in 2009, rural poverty was around 24.6% (MOP 2013), and 19% of reproductive-aged women were underweight (NIS 2010). In 2010, 40% of children under 5 years of age were stunted, 11% were wasted, and 28% were underweight (see Table 1 for some socioeconomic characteristics of the study population in the FTF provinces in Cambodia for various years since 2010). In Pursat, one of the study areas for this evaluation, the percentage of children younger than 5 that were stunted, wasted, and underweight in 2010 was as high as 45, 13, and 31, respectively (Table 1).

Cambodia’s high levels of malnutrition reflect serious problems with all three dimensions of food insecurity: availability, access, and utilization of food (i.e., dietary choice and water, health, and sanitation practices). Eleven percent of Cambodia’s total population is estimated to be chronically food-insecure, with an added 7% dropping into food insecurity during the lean seasons (World Food Program 2008). Despite rice production surpluses at the national level, at the household level Cambodians face poor production, storage, and availability of affordable rice and other foods. These constraints restrict the ability of farm households to maintain or increase the value of their production.

3 This section heavily borrows from the USAID/Cambodia FTF Strategy document.

4 The new approach for estimating the poverty line, announced by the Ministry of Planning in April 2013, significantly affects poverty rate measurement in Cambodia. In 2011, Cambodia’s overall poverty headcount was about 19.8%, and in 2014 it was 18.8% (see Table 1).
Poor dietary choices by Cambodians at all income levels reflect traditional beliefs and poor knowledge of nutrition, water and sanitation needs, and proper child feeding practices. Appropriate use of supplemental, weaning, or complementary foods for infants and small children is also low. The country also faces the problems of lack of clean water and appropriate sanitation practices. The United Nations estimates that up to 50% of malnutrition could be eliminated in places like Cambodia if water and sanitation issues were adequately addressed. However, this requires persuading households to make the choice to invest in affordable water and sanitation by educating them on the health, nutrition, and economic benefits of using these practices.

The agricultural sector in Cambodia suffers from low productivity and high postharvest losses, particularly in rice and vegetables (Vuthy et al. 2013). The majority of Cambodia’s agricultural production is dependent on rain and highly vulnerable to both flood and drought. Despite these risks, most food-insecure farming households in Cambodia rarely diversify production from wet-season rice and fish. Food and income shortages in the lean season force labor migration to the urban areas, which reduces the workforce needed to maintain farms. Overall household poverty increases the likelihood that male labor migration will take place and thus increases the number of poor, female-headed households, which make up 69% of rural poor households. The labor constraint created by this shift decreases women's time to participate in training or other activities designed to improve farm production and sales.

Under the FTF initiative, USAID made genuine efforts to address some of these challenges by engaging closely with the Royal Government of Cambodia. Studies have shown that families that have a diversified portfolio of production and income sources tend to be better able to withstand economic or climatic shocks to their farms and households. Thus, diversification is considered critical for reducing poverty and malnutrition in Cambodia’s rural areas, and this was one of the principles underlying the ‘comprehensive’ approach promoted under Cambodia HARVEST. The project strategy toward development is described below.

2.2. Cambodia HARVEST: Scope, Scale, and Achievements

Funded at US$56.8 million and implemented by Fintrac, Inc., Cambodia HARVEST was a 5½-year (2010-2016) development project focused on improving food security for more than 124,000 rural Cambodian households as part of the U.S. government’s Feed the Future and Global Climate Change initiatives. The project targeted three primary sectors: agriculture, fisheries, and forestry, and took a comprehensive approach in promoting three value chains—rice, horticulture, and aquaculture. It developed sound, agriculture-focused solutions to address some of the challenges noted above, such as poor productivity, postharvest losses, malnutrition, lack of market access, environmental degradation, and the effects of climate change on vulnerable rural populations.

A midterm performance evaluation of Cambodia HARVEST was undertaken in 2013, after 35 months of program implementation (Gray et al. 2013). The evaluation indicated that Cambodia HARVEST placed major emphasis upon increasing the availability of food (component I), and considerable effort went into the development of commercial horticulture, in particular. Rice and fishery activities tended to contribute to increased income. Home gardens were viewed primarily as sources of cash rather than additional food. Their direct impact on improved food consumption appeared to be less than might be expected.
The midterm performance evaluation also indicated that component 2 (increased food access through rural income diversification) was less effectively addressed. Few of the off-farm income-generating activities were making a significant impact on incomes, and beneficiaries reported that their time was better spent in other activities.

The midterm evaluation also reported that the nutritional aspect of Cambodia HARVEST had been well developed within the constraints of available resources, and a reasonable degree of coverage of beneficiaries had been achieved. The utilization component of food security had been addressed through nutritional training, but more needed to be done in this area.

The midterm evaluation made the following recommendations to improve the program’s effectiveness and impacts:

- Cambodia HARVEST interventions were not well-suited to benefit the ultra-poor or extreme poor, poor youth, illiterate, and elderly effectively. Thus, separate interventions should be developed for the poorest households.
- Sustainable, market-oriented, self-financing community forestry and community fisheries should be developed in ways that provide equitable sharing of benefits and costs by the poorest segments of fishing communities.
- The program should proactively seek out and develop alternative options for the provision of technical assistance to growers and producers once Cambodia HARVEST is completed.
- The program should increase inclusion of youth in its recruitment of participating clients and other forms of beneficiary identification.
- A more effective working relationship between the Royal Government of Cambodia and Cambodia HARVEST staff members was needed at all levels.

On the basis of recommendations from the midterm performance evaluation, the Cambodia HARVEST team modified and/or adjusted some of its implementation strategies. Overall, Cambodia HARVEST’s strategy remained focused on providing technical assistance and training to farmers, input suppliers, processors, and traders throughout the value chain. Program clients from 1,476 villages across four provinces (Battambang, Pursat, Siem Reap, and Kampong) around the Tonle Sap Lake received training in production practices, postharvest value addition, business skills and marketing, natural resource management, and improved health and nutrition practices. Figure 1 shows the geographic distribution of Cambodia HARVEST target villages. In each project village, Cambodia HARVEST formed farmers’ groups for commercial-scale rice production, high-value commercial horticulture, and the promotion of kitchen gardens. In certain communities, HARVEST also targeted aquaculture (low-input and high-input ponds), fisheries, and forestry sectors using similar client household groups as the primary intervention mechanism. The program also incorporated cross-cutting activities on social inclusion (women, youth, and the extreme poor), nutrition, and the environment. Table 2 gives an overview of the number of villages, clients, groups, and total beneficiary households affected by the project over the life of the project by types of activities.

---

5 The HARVEST project defined the following types of program clients who received different types and intensities of project interventions: demonstration client—farmer or individual who demonstrated program techniques and technologies to nearby farmers under a co-investment agreement; partner client—communities or agribusinesses assisted by the program; producer group—a number of farmers who come together to leverage market options; beneficiary—farmers or individuals who receive indirect technical assistance from the program; participants—farmers or individuals who attend trainings (Fintrac 2016a).
Using a comprehensive and intensive extension methodology to deliver hands-on technical assistance to smallholder farmers (including women and youth) and other program clients, Cambodia HARVEST aimed to: increase food availability by increasing productivity through the introduction of improved technologies and practices; increase food access through rural income diversification; improve natural resource management and resilience to climate change by working with local governments and other partners to manage protected areas and natural resources and to implement climate-smart agricultural technologies; and expand the capacity of public, private, and civil society to address food security and climate change challenges. According to Fintrac (2016b), during the life of the project, the Cambodia HARVEST team collaborated with six government ministries, 99 other government entities, 20 donor organizations, five educational institutions, and 705 private sector firms.

Overall, more than 345,000 people received training in agriculture and food security through these various interventions. According to the project’s final report, Cambodia HARVEST was able to meet or exceed nearly every program target, including the development of a burgeoning domestic horticulture industry. The infographic in Annex 1 presents a summary of selected indicators of program achievements based on the project’s internal monitoring and evaluation data.

3. CONCEPTUALIZING PATHWAYS FROM HARVEST INTERVENTIONS TO IMPACT ON FTF GOALS

Cambodia HARVEST was the flagship project of USAID/Cambodia under FTF. Therefore, it is useful to review the Feed the Future results framework and how Cambodia HARVEST contributed to the overall FTF goals and objectives. The FTF results framework highlights two main objectives: inclusive agriculture sector growth and improved nutritional status for women and children. Cambodia HARVEST aimed to contribute toward these two FTF objectives by integrating nutrition as one of the cross-cutting components in its agriculture-focused interventions. This approach is guided by the belief that mutually supporting programs of nutrition and agriculture will be more effective in improving nutritional status than either of the components on its own.

In Figure 2, we present the pathways through which the comprehensive strategy of Cambodia HARVEST is conceptualized to influence the agricultural growth and nutritional outcomes in the context of farm households of the type targeted by the project. The four types of project interventions are conceptualized to influence individual and farm household behavior change, adoption of practices, and women’s empowerment, which can lead to agricultural growth (as reflected in increased productivity, diversification, input availability, sales of produce, and storability, safety, and quality of food), increased production and income, and ultimately improved food security and nutrition outcomes through increased expenditures and adequate and diverse food intake. This framework also highlights the causal linkages between various types of results (or FTF indicators focused on by this evaluation) along the pathways from agriculture to improved nutrition.

A variety of approaches are used in the literature to conceptualize causal pathways from agriculture to nutrition and health (see Webb 2013, for a review). Most of these approaches are based on conceptual frameworks that build on the understanding that agriculture can influence nutrition and health through multiple pathways (direct and indirect), and that food alone is not enough. For example, Headey, Chiu, and Kadiyala (2011) and Gillespie, Harris, and Kadiyala (2012) talk of seven pathways, which include agriculture as the direct and indirect (via income) source of food at the household level. Other pathways include macro-level agricultural policy as a driver of prices and agriculture as an entry point for enhancing women’s control over resources, knowledge, and status. The frameworks by Hawkes, Turner, and Waage (2012) and Chung (2012) elaborate on elements not frequently highlighted, such as micronutrient deficiency versus anthropometry, nutrient quality/bioavailability, food value chains, and demand creation for health services through knowledge and nutrition education.

The framework presented in Figure 2 highlights three main pathways linking agriculture to nutrition: food production, agricultural income, and women’s empowerment (depicted as pink boxes in Figure 2). Food production affects a household’s nutritional status through the type, quantity, and seasonality of food available for consumption (Chung 2012; Herforth and Harris 2014). That is, the broader food market environment influences a household’s decision of what to produce and consume. If a preferred food is not available or affordable in the local market, a household may instead choose to grow that crop on their farm (Herforth and Harris 2014). As a second pathway, an increase in agricultural income could result in increases in food expenditure, which could result in higher levels of dietary diversity and more food consumption and food security overall. More income could also translate into higher non-

---

6 See Feed the Future Results Framework
7 A fourth pathway not depicted or discussed in this paper is food prices, which can affect net purchasing power of households depending on whether they are net buyers or net sellers of food (Carletto et al. 2015).
food expenditure, including expenditure on health care, which could directly raise a household’s nutritional status. This pathway is based on the assumption that income and nutrition are related. For example, the quality, quantity, and diversity of food consumed is usually better and child nutrition is more adequate in wealthier households than in poorer ones. However, the correlation is not always linear and as strong as might be expected.

Figure 2. Pathways of Effects of Cambodia HARVEST Interventions on Income, Food Security, and Nutritional Outcomes

Source: Authors’ compilation.
The realization of this pathway rests on several assumptions about the intrahousehold dynamics and external conditions (i.e., food markets, social norms, infrastructure, institutions, etc.) that influence behavior of individuals and their decisions on how they use income. In general, evidence suggests that this pathway alone will likely have modest impacts on malnutrition unless it is also accompanied by improved health and education outcomes (Carletto et al. 2015; World Bank 2007; Bhagowalia, Headey, and Kadiyala 2012; FAO 2013; Ecker, Breisinger, and Pauw 2011).

Women’s empowerment, as a third pathway, emphasizes women’s combined roles in agriculture, dietary choices, and healthcare, and their influence on nutritional outcomes for both child and mother (Malapit et al. 2015) (Figure 2). The emphasis on women’s empowerment in these pathways is supported by the evidence that suggests that income controlled by women has a greater positive effect on children's nutrition than that controlled by men (Herforth, Jones, and Pinstrup-Andersen 2012). Empowering women through targeted agricultural interventions can thus have a strong positive effect on child nutrition and household food security (Hawkes and Ruel 2008).

As a comprehensive and nutrition-focused development project, Cambodia HARVEST interventions were designed to influence all three pathways linking agriculture to improved food and nutrition security—food production, crop income, and women’s empowerment. Higher crop productivity caused by the adoption of new technologies and practices promoted by Cambodia HARVEST would make more food available for sale and consumption, thus potentially influencing both production and income pathways. Moreover, a production system that includes a greater variety of foods, as encouraged by Cambodia HARVEST, provides households a greater diversity of food for their consumption. For example, the study by Jones, Shrinivas, and Bezner-Kerr (2014) indicates that a more diverse production system (measured with a simple crop count, a crop and livestock count, and a Simpson’s index) was positively and significantly correlated with dietary diversity indices and with the number and frequency of legumes, fruits, and vegetables consumed.

Within the framework shown in Figure 2, we explore some of these effects of the Cambodia HARVEST through this impact evaluation, albeit controlling for the confounding factors that can potentially influence or constrain these linkages. The interventions specifically focused on in this evaluation are the first two sets of activities described in Figure 2. These interventions encompass promotion of improved technologies and practices within the rice, horticulture and fish value chains, agriculture-nutrition linkages, and access to credit and marketing assistance. Specifically, the impact evaluation focuses on Cambodia HARVEST clients that participated in the home garden, rice, or aquaculture value chain activities who could also have received indirect technical assistance from the program or participated in other training programs (e.g., nutrition education, cooking demonstration, savings fund program, community forestry, etc.). We examine the status of and change over time in selected FTF indicators that represent various nodes along this pathway (depicted by the solid red line in Figure 2. They include: production and income (measured by gross margins), expenditure, diversity of food intake, and nutritional outcomes. Specifically, we test the following hypotheses:

Farm households that participated as clients and received Cambodia HARVEST interventions (i.e., technical assistance, extension services, training, field demonstrations, etc.) would have:

1) Greater availability of food as measured by total production (food production pathway).
2) More income from production as measured by net income and total expenditures (income pathway).
3) More diverse diets and improved nutritional outcomes for children and women (a combination of production, income, and women’s empowerment pathways).

The objectives of this independent evaluation report are to:
1) Present the results of the endline survey conducted in Cambodia HARVEST targeted villages (to promote rice, horticulture, and fish value chains, and nutrition programs) to assess whether and by how much project outcome status (of some key FTF indicators along the impact pathway) improved for Cambodia HARVEST clients compared with the baseline
2) Present the results of the impact evaluation of project interventions using rigorous methodologies that take into account counterfactuals and selection bias issues to assess whether the observed changes in outcome status of client households can be attributed to Cambodia HARVEST.

Methodology and data for the descriptive analysis (objective 1) and impact analysis (objective 2) are described next, followed by the presentation of results and discussion.
4. DATA AND METHODOLOGY

4.1. Data Sources and Impact Evaluation Strategy

In anticipation of the impact evaluation to be done at the end of the Cambodia HARVEST project, a baseline survey was conducted in 2012\(^8\) by the Cambodia Development Resource Institute (CDRI), a leading independent development policy research institute with extensive experience in survey research, data entry, and data analysis.\(^9\) Data were collected from 1,500 farm households representing 60 Cambodia HARVEST villages selected randomly from a list of villages provided by the Cambodia HARVEST team that were to receive project interventions as clients or demonstration leaders. This sample of 1,500 households forms the definition of treatment group for this evaluation. According to impact evaluation design, an additional 600 households representing 24 comparison villages that were projected not to receive any Cambodia HARVEST intervention were to be surveyed to represent the comparison group (Suvedi 2012). The village list for the comparison group was also provided by Cambodia HARVEST, but CDRI researchers developed the list of households for sample selection. The sample selection strategy for the 2012 survey is detailed in the baseline report and summarized in Annex 2 (Vuthy et al. 2013). From each selected treatment village, 25 households were randomly selected from the list of households identified by Cambodia HARVEST as client households targeted to participate in rice, home garden, or aquaculture activities. Table 3 shows the composition of sampled households by the type of Cambodia HARVEST interventions they were targeted to receive.

The 60 Cambodia HARVEST villages (15 per province) selected for the survey in 2012 represented approximately 15,000 households targeted to receive direct interventions from Cambodia HARVEST on rice, horticulture (mostly home gardens), and fish value chains, nutrition education and demonstration programs, and exposure to credit access and marketing services. At the time the baseline survey was conducted in August-October 2012, the project had only a list of villages that were already reached in 2011 and 2012 and villages to be targeted in 2013. In selecting the treatment villages for the baseline survey, all the villages that had already received interventions that would have affected the 2011–12 agricultural production cycle were dropped. The project did not have a list of villages to be targeted beyond 2013. The sample of treatment villages selected for the impact evaluation, thus, represents only the early cohort of intervention villages. Over the 5½-year, the Cambodia HARVEST’s strategy had evolved in response to the midterm review and other internal learning that happens in scaling up project activities. Unfortunately, the sample of villages selected in 2012 for this evaluation does not capture this evolution of the Cambodia HARVEST’s strategy and focus over time.

---

\(^8\) Referrred to as Cambodia HARVEST Impact Evaluation Baseline Survey.

\(^9\) It should be noted that Cambodia HARVEST had already sub-contracted CDRI for the baseline survey and MSU’s role was limited to providing technical assistance.
Six comparison villages from each province (total 24 villages) were randomly selected from a list of villages provided by Cambodia HARVEST. These comparison villages were located near Cambodia HARVEST districts and villages that were not being considered for Cambodia HARVEST interventions but had similar socioeconomic characteristics, crop and fishery operations, road infrastructure, and soil and climatic conditions. Twenty-five households within the treatment and comparison villages were randomly selected to represent rice, vegetable, or fish farming households. However, one of the villages selected as a member of the comparison group eventually received Cambodia HARVEST interventions. This necessitated classifying this village as a treatment village in the analysis presented in this report.

GPS coordinates data obtained from CDRI in 2016 for the comparison villages indicate their close proximity to treatment villages selected for the evaluation (see Figure 3), which is both good and bad. Close proximity to treatment villages ensures comparability on several socioeconomic and agroclimatic factors that can influence outcomes, but it also increases the potential for contamination from spillover effects of project interventions from treatment to control villages (Bloom 2007). On the basis of the GPS coordinates data obtained in 2016, we estimated that the average distance between the comparison villages and the closest selected treatment villages was 4.2 kilometers (km), and the distance between the comparison villages with the closest Cambodia HARVEST intervention village was 1.4 km. This close proximity of comparison villages from the Cambodia HARVEST treatment villages raises concerns about spillover effects, which can dilute the potential program effect.\textsuperscript{10}

In 2016, the same 2,100 households were revisited to complete an endline survey (Cambodia HARVEST Impact Evaluation Endline Survey) around the same time frame as the baseline survey was conducted four years before (i.e., August-October). However, attrition of 179 households (124 HHs in the treatment group and 55 HHs in the comparison group) reduced the total number of reinterviewed households from 2,100 to 1,921 (Table 4).\textsuperscript{11}

To take into account some expected attrition of the original sample and to increase the sample size, especially of children under 5 years of age, an additional 407 households (307 HHs in treatment and 100 HHs in comparison group villages) were also included in the 2016 survey.\textsuperscript{12} These additional households were randomly selected from the same 84 villages from a list of households that met the following criteria: households that were not surveyed in 2012, had children less than 5 years age, and were either beneficiaries or met the Cambodia HARVEST eligibility requirements (i.e., grew rice or horticulture crops or was involved in aquaculture). Thus, for the 2016 survey, we have data for 2,328 households (Table 4).

\textsuperscript{10} The guidance from MSU (Suvedi 2012) on the selection of comparison village was to avoid selecting villages in close proximity to the treatment villages to avoid spillover effects and potential contamination (which occur when the outcomes for some program participants influence those for other participants or for people who are not participating in the program (Bloom 2005)). The guidance given by MSU was that villages adjoining Cambodia HARVEST activity villages or where interaction between treatment and comparison villages took place on a regular basis should not be selected as comparison group villages. However, it seems that this guideline was not followed when the comparison villages were selected in 2012 or later when the HARVEST project expanded its activities and subsequent cohorts of villages were selected for interventions (see Figure 1), which reduced the average distance between the comparison and closest treatment village to only 1.4 km.

\textsuperscript{11} Sixty-nine of these 179 households were replaced in Battambang Province, and the other 110 households were replaced in Pursat, Siem Reap, and Kampong Thom. The highest replacement per village was six households. The most common reason for replacement was migration of the whole family to other places, or the migration of all adult members. Only for three households was the reason for replacement their refusal to be reinterviewed.

\textsuperscript{12} This includes 179 replacement households and 228 new households to increase the sample size (three households per treatment group villages and two households per comparison group villages).

a. Includes households from villages that were originally under the comparison group but had received HARVEST interventions after the 2012 survey.

The household survey questionnaire included modules that required collecting food consumption and anthropometrics data, and other food/nutrition-related information from all women 15-49 years of age and required measuring the height and weight of all children less than 5 years of age. Table 5 shows the number of women and children for whom we have individual-level data as against the number of all eligible women (some households have more than one eligible woman) and children reported in the household roster in 2012 and 2016 surveys. The response rate of women was about 83-84% in 2012 and increased slightly to 87-88% in 2016. The main reason for the missing data for women was their unavailability (or absence) at the time of the interview. Most eligible children (i.e., children less than 5 years age) were present for height and weight measurements, and data on their food consumption were collected from their caregivers.

Both the 2012 and 2016 surveys were conducted by CDRI. Technical assistance on the sampling strategy and questionnaire design for both the surveys was provided by Michigan State University.¹³

Several features of this dataset and how it relates to the actual Cambodia HARVEST implementation need to be highlighted because they have implications on the impact evaluation strategy used (or not used) in this study. First, the survey data on which the impact analysis is based were collected from villages and households that were not randomly assigned to receive or not receive the Cambodia HARVEST interventions. Thus, they represent observational data rather than experimental data. Simple mean comparison of outcome indicators between the two groups will give biased estimates of project impacts. Thus, we employ several econometric estimation strategies to control for placement and selection bias. The evaluation design basically takes a quasi-experimental evaluation approach using the panel dataset (2012 and 2016) from the treatment and comparison villages.

Second, by the time the 2012 survey was planned, only 149 villages were identified by Cambodia HARVEST to receive interventions, and the selection of treatment villages for this evaluation was restricted to this list of 149 villages provided by the project. By the time the project ended in 2016, a total of 1,476 villages were reported as having received project interventions (Fintrac 2016b). The data used for this impact analysis is thus only representative of the first and second cohorts of villages targeted by Cambodia HARVEST. The project strategy (types of intervention) evolved over the five-year period, which is not captured in the village sample selected for this evaluation. For example, the emphasis on commercial horticulture increased in subsequent cohorts of villages, and home gardens were deemphasized. Caution must be used in generalizing the results to all Cambodia HARVEST intervention villages.

¹³ Questionnaires used in the 2012 and 2016 surveys along with the anonymized dataset will be soon available at the USAID Development Data Library (DDL) website.
Third, many government and donor-funded programs were active in the four provinces of Cambodia targeted by Cambodia HARVEST (i.e., the FTF zone of influence), and there was a high chance of exposure to other types of interventions by households in the comparison villages.

Fourth, after about 18 months of operation, Cambodia HARVEST activities were suspended in three districts in Siem Reap Province because these districts were targeted to receive similar services through another donor-funded project.

Further, Cambodia HARVEST clients received technical assistance on rice production, home gardens, and/or aquaculture for a period of 18 to 24 months, and the project staff moved to the next set of target villages. After the Cambodia HARVEST activities were concluded, the households might also have received services from other NGOs. This means that the intervention and comparison villages are not truly treatment and control villages in the experimental sense. This necessitated controlling for this potential exposure effect (from other interventions) in both the treatment and the comparison groups.

Finally, treatment households in the baseline survey were selected from a list of households provided by Cambodia HARVEST that were targeted to receive interventions in 2012 or 2013. However, not all the households selected in the baseline survey actually received the interventions as intended or graduated from the program as planned. To make sure that only those households that actually received and had completed the Cambodia HARVEST interventions are included in the analysis (i.e., to estimate the average treatment effect on treated, rather than the intent to treat treatment effects), the list of surveyed household members was compared with the list of Cambodia HARVEST clients and beneficiaries, obtained from USAID/Cambodia. On the basis of the comparison of the project participant list and the baseline survey list for panel households, a total of 1,381 households were matched (Table 6). Out of these 1,381 households, 108 households had participated only as activity participants in Cambodia HARVEST, and not as clients. In addition, the status of 185 client households was reported as inactive as of September 2015. For future program design implications and investment guidelines and to evaluate the effects the project had on the client beneficiaries, it makes sense to estimate the average treatment effect on the treated (ATT) on only the households that actually participated in Cambodia HARVEST or did not become inactive. We thus use two analytical samples to estimate the ATT as noted in Table 6.

Sample 1 includes only client households that were active or had graduated from the Cambodia HARVEST interventions as of September 2015, and it can be considered the true treatment sample. However, 312 household samples from the treatment group were dropped from the analysis, which can potentially reduce the statistical power for detecting an impact within a reasonable margin of error and a high confidence level. Thus, to increase the sample size, in sample strategy 2 we include all the client households irrespective of whether they graduated or dropped out of the program. This increases the sample size of the treatment group from 1,088 in sample 1 to 1,273 in sample 2. The estimation of average treatment effect based on sample 2 will tend to underestimate the true effect of the program. Note that the treatment effects estimated using samples 1 and 2 both suffer from placement or selection bias. We describe below the methodology used to estimate these effects and the identification strategies used to address the bias issues.

4.2. Identification Strategy

The purpose of conducting this impact evaluation was to determine the extent to which the Cambodia HARVEST activities in the selected villages actually caused any observed changes in outcomes along the impact pathway noted in Figure 2. The monitoring data collected by Cambodia HARVEST or the baseline and endline survey data analysis for the treatment group reported in this study in the descriptive section are important tools to track the performance indicators. However, comparing data on performance indicators for the beneficiaries against the baseline values demonstrates only whether change has occurred, with very little information about what actually caused the observed change. Analysis based on such data can only indicate the direction of change in outcome and whether the program is correlated with those changes, but it cannot confidently attribute that change to Cambodia HARVEST. This impact evaluation was thus designed to assess whether and how much the client households that participated in the rice, aquaculture, and home garden value chain experienced a change in productivity, sales, income, expenditures, poverty status, dietary diversity, and nutritional outcomes as a result of Cambodia HARVEST. Unlike general evaluations, which can answer many types of questions, this impact evaluation was structured around one particular type of question: what are the impacts (or causal effects) of Cambodia HARVEST on client households that participated in at least one of the targeted value chains.
(rice, aquaculture, or home gardens) on outcomes of interest? For example, did the technical assistance programs on rice, home gardens, and aquaculture value chains in the targeted districts in Cambodia cause gross margins to increase, expenditures to go up or poverty rate to go down? Did these interventions in combination with the nutrition-focused activities cause an increase in dietary diversity or reduce the prevalence of stunting, wasting, and underweight among children younger than 5 years of age?

To measure these causal effects, we planned to compare the outcomes of the targeted group in the presence of the program (i.e., treatment group) relative to the outcomes if the program had not been implemented. In other words, the basic principle that guided our evaluation approach is the comparison between situations with the project activities and without the project activities, also known as treatment effect. This is as opposed to merely comparing beneficiaries before and after the project implementation (i.e., assessing the change in the situation of the beneficiary before and after or simply assessing the difference between participants and non-participants). Unfortunately, it is not possible to compare the same population in both the states—with and without program exposure.

Practically, to address this problem, we estimated the average impact of the program on a group of individuals by comparing them to a similar group of individuals not directly affected by the program. Therefore, one critical step of any impact evaluation exercise is to establish a credible comparison group. A number of empirical approaches have been employed to establish the credible comparison group (or control group). The most robust approach is randomization—the treatment group and the control group are randomly selected from all the eligible sampling units (either clusters or individuals). A randomized experiment guarantees that there are no differences in the observed and unobserved characteristics (on average) between the treatment and control groups, and thus a statistically significant difference in outcomes between the two groups can be attributed to the program. However, as noted before, this strategy was not feasible or compatible with the implementation strategy of Cambodia HARVEST.

Thus, we adopted the quasi-experimental strategy of comparing the treatment and comparison groups (based on the propensity score matching [PSM] method) and estimating the difference-in-difference (DiD) estimator for effect identification.

### 4.2.1. PSM-DiD Approach

Under the PSM-DiD approach, units of observations (i.e., households) from the treatment villages are matched to units of observations from the comparison villages (those not targeted by Cambodia HARVEST), and outcomes are compared between these two groups before and after the intervention. Examining how outcomes change for households in the comparison group that were not exposed to Cambodia HARVEST will inform us about how those outcomes would have differed in the absence of the intervention for the treatment group. This approach is used for two definitions of treatment sample—the treatment sample that included only those households in the panel sample that had graduated or were active as of September 2015 (sample 1); and the treatment group that included all the client households, including those that started with the program but became inactive (sample 2).

The DiD approach essentially measures the difference of outcome indicators between beneficiaries (treatment group) and non-beneficiaries (comparison group) before and after program intervention. In the context of panel data, DiD is a common and valid method to
estimate the impact of an intervention if the assumption that unobserved heterogeneity is time invariant and uncorrelated with the treatment effect is satisfied. While the main advantage of DiD is its ability to allow for selection on unobserved factors, its assumption of constant selection bias over time may be unrealistic in practice.

Let Y be the outcome of interest (e.g., gross margins, total expenditures, poverty status, stunting, underweight, etc.). Our goal is to evaluate the impact of the Cambodia HARVEST intervention \( T \) on \( Y \) after a time period 1. Specifically, we can achieve this evaluation through DiD as

\[
DD = E[Y_{1T} - Y_{0T}] - E[Y_{1C} - Y_{0C}]
\]

where the superscripts \( T \) and \( C \) refer to treatment and control households, respectively; the subscripts 1 and 0 refer to time period 1 (after the intervention) and time period 0 (the baseline period), respective; \( T=1 \) refers to treatment group. The regression counterpart of (1) is the following:

\[
Y_i = \alpha + \beta T_i + \gamma t + \delta(T_i*t) + \epsilon_i
\]

where \( T_i \) is the dummy to distinguish treatment group \( (T=1) \) from control group \( (T=0) \), \( t \) is a time dummy \( (t=0 \text{ for before treatment and } t=1 \text{ for after the treatment}) \), and \( \epsilon \) are the idiosyncratic error terms. The coefficient of interest is \( \delta \), which measures the DiD treatment effect. In (2), we can further add other control variables \( (X) \) to increase the efficiency of the estimation.

\[
Y_i = \alpha + \beta T_i + \gamma t + \delta(T_i*t) + \phi X_i + \epsilon_i
\]

DiD is widely used in impact evaluation of development interventions, especially when the experimental data are not available (see discussion by Duflo, Glennerster, and Kremer 2007; Ravallion 2001.

In this study, we used this DiD estimation strategy to estimate the intent to treat treatment (ITT) effect, which measures the average effect of Cambodia HARVEST interventions across all the sampled households in the treatment villages irrespective of the type and intensity of participation in Cambodia HARVEST program activities compared with the effects across all the sampled households in the comparison villages. The ITT is interpreted as the effect of giving someone an opportunity to receive program interventions. The ITT is particularly relevant in assessing programs and interventions like Cambodia HARVEST where participation in various activities may be voluntary.

The treatment villages were purposively selected by the Cambodia HARVEST team, and the clients and beneficiaries from within these villages were not randomly assigned to particular interventions (i.e., participation may have been voluntary or targeted to specific households). This creates the problem of placement bias and self-selection bias. Basically, this means that the treatment and comparison groups may be different in many aspects that can influence the outcomes, and therefore, simple comparison of mean outcomes will generate biased estimates of treatment effects. To correct for this bias, at least on observable characteristics, we adopted the propensity score matching method to first create treatment and comparison groups that match on propensity score.

Propensity score matching (PSM) uses observed characteristics to construct a statistical comparison group that is based on a model of the probability of participating in the program.
intervention. Households from the treatment group are then matched on the basis of this probability, or propensity score, to households from the comparison group. The ITT effect of the program is then calculated as the mean difference in outcomes across these two groups, before and after the interventions are implemented. The validity of PSM depends on two conditions: conditional independence (namely, that unobserved factors do not affect participation) and sizable common support or overlap in propensity scores across the treatment and comparison samples (Rosenbaum and Rubin 1983; Caliendo and Kopeinig 2008; Guo and Fraser 2010).

PSM attempts to mimic randomization by creating a sample of households that received Cambodia HARVEST interventions that is comparable on all observed covariates to a sample of households that did not receive the project interventions. The purpose of using this statistical technique is to reduce the selection bias by equating groups of households that share similar observable characteristics. Regression-based methods on the sample of program treatment and comparison households, using the propensity score as weights or including propensity scores as a covariate, can lead to more efficient estimates.

The matching is done at the household level, which means many parcel-, individual- and crop-level characteristics are converted into household-level variables. The propensity scores are estimated at the household level using a logistic equation expressed as:

$$H_i = a + bX_i + \varepsilon_i$$

where \(H\) can take only two possible values – 0 and 1 – and \(X_i\) is the observable characteristic of the household. Details of observable attributes incorporated in the logistic regression include demographic conditions and other household characteristics such as farm assets and household assets, and the selected \(Xs\) should be unaffected by participation in the project (\(X\) should not include assessment indicators).

The regression is followed by a prediction of propensity scores expressed as:

$$p(X) = \Pr(H_i = 1|X = x_i)$$

This generates a single number \(p\) between 0 and 1, which represents a household’s probability of being selected for the Cambodia HARVEST intervention regardless of whether a household was in the treatment or comparison group. Each of the households in the treatment group is then paired up with one or more households from the comparison group with a similar propensity score. This matching can be conducted using various matching algorithms, such as nearest neighbor (NN), caliper and radius, stratification and interval, kernel, and local linear. In this study, we used the NN and kernel matching methods to construct the matched samples.\(^{14}\) Households whose propensity scores were not comparable (not in common support) were dropped from the analysis, which kept only the households that are on common support for the impact estimates in the DiD method.

The matching method described above creates two groups of households – households that were targeted to receive project interventions and households with similar propensity scores that were not targeted for the interventions. Because the propensity score weights the

\(^{14}\) Caliendo and Kopeinig (2008) conclude that there is no best algorithm for all situations because the choice eventually depends on the existing data and situation. The performance of different matching estimators varies case by case and depends largely on the data structure at hand (Zhao 2003).
importance of the different characteristics of the households \((X)\), the result of the matching process is that, on average, the differences between the households from the treatment group and the matched households from the control group are much smaller than the differences actually observed between the two groups in the sample.

The quality of the matching can be assessed by two metrics: the common support region (or overlap region), which measures how well the estimated propensity scores for the treatment households and the control households overlap each other, and the degree to which the covariates are balanced between the treatment and control groups before and after matching. After matching, it is expected that there will be no significant differences in characteristics \(X\) (control variables) between groups. To assess the matching quality, we checked the standardized bias of each independent variable in the logistic regression before and after matching. Most empirical studies argue that standardized mean bias below 3% or 5% after matching is sufficient (Caliendo and Kopeinig 2008).\(^{15}\) The propensity scores resulting from the PSM estimations are used in the DiD regressions as one of the control variables.

The PSM-DiD models are estimated using the common fixed effects (FE) assumption that the household-specific effect is correlated with the independent variables. However, the main drawback of FE model is that it is impossible to estimate the impact of time-constant variables (e.g., the propensity score and program participation status). One way to address this limitation is to use the correlated random effect (CRE) approach proposed by Mundlak (1978) and Chamberlain (1984) which allows us to include the time-constant variables (such as propensity score and program participation status) and at the same time delivers the FE estimates on the time-varying covariates (e.g., age, gender and education of head of the household, household size, assets, land holdings, etc.). Two key assumptions for the CRE estimates to be unbiased and consistent are strict exogeneity of the covariates relative to the idiosyncratic errors and that the time-constant unobserved household-level heterogeneity be a linear function of the household time averages of the observed covariates, such that including these time averages as additional covariates in the regression effectively controls for the unobserved heterogeneity (ibid.). Thus for robustness check, in this study we estimate and report the program effects using both the CRE and the FE model assumptions.

---

\(^{15}\) The results of the PSM for the two sets of samples used to estimate the treatment effect are reported in Annex 6.
5. RESULTS: DESCRIPTIVE ANALYSIS

5.1. Type and Intensity of Program Participation by the Treatment Group

Before we discuss the characteristics of the sampled households and a summary of outcome indicators, it is important to describe the type and intensity of program participation by the treatment groups based on the two analytical samples defined in Table 6. Toward this goal, we present in Table 7 the scope and intensity of project participation by the treatment households, as defined by samples 1 and 2, by the gender of the household head. Overall, about two-thirds of the households participated as clients for home gardening, about 50% in the rice value chain, and about 20% in the aquaculture value chain. For all types of interventions, the rate of participation was higher among male-headed than female-headed households.

Cambodia HARVEST was designed to provide technical support to client members for 18 months, after which the members would graduate from the program. Although a household could participate in multiple value chains, one member could participate in only one value chain as a client. As shown in Table 7, on average, about 1.3 male members and 1.6 female members per household participated as clients of Cambodia HARVEST. The participation of members from a male-headed household was higher than the participation from female-headed households. Also, the intensity of participation was comparatively higher for male-headed households as measured by participation in the number of client and other activities, number of years participated, and average number of Cambodia HARVEST activities in which they participated.

By definition, 100% of client households in sample 1 had members who had graduated or were active Cambodia HARVEST participant as of September 2015. This percentage is about 86 for sample 2 (because it includes 185 households that started as clients but did not complete the program). About 12% of households in sample 1 and 24% of households in sample 2 had at least one client member whose status was reported as inactive as of September 2015. In sample 1, the percentage of inactive members was higher in male-headed than in female-headed households. On average, over the 3 years, a client household participated in about 1.3 to 1.4 interventions out of the three focused in this evaluation—i.e., home garden, rice and aquaculture value chain. The households sampled for this evaluation mostly received the interventions in 2012 and 2013, but some households who were still actively participating in client activities in 2014 and 2015, even though the project was rolled out and expanded to other villages each year. Thus, for the sample of households included in this evaluation, the endline survey data collected in 2016 represents on average a lapse of about two years since HHs’ participation in Cambodia HARVEST as clients. This is enough time to observe some short- to medium-term effects of the treatment they had received from Cambodia HARVEST.

5.2. Household Characteristics

Table 8 presents selected household characteristics of treatment and comparison group villages for sample 1, which uses the stringent definition of treatment group as defined in Section 4.1. These include household demographics, land ownership and use, ownership of household assets, and household income sources. The 2016 data are presented by the gender of the head of the household for panel households that were surveyed in 2012 and reinterviewed in 2016. In Table 9, we present the 2012 data for the same panel households for the same variables noted in Table 8. Similar descriptive tables for sample 2 are included in Annex 3.
| Table 7. Participation in Various Types of Activities by Client Households in the Treatment Group (Samples 1 and 2) by the Gender of the Head of the Household |

Source: Cambodia HARVEST Impact Evaluation Baseline Survey, 2012. MHH=Male-headed HHs, FHH=Female-headed HHs, n=Number of observations; t-test: **= p<0.01, *=p<0.05.
On average, the households in our sample had five to six members, half of whom were women; 40% were women of child-bearing age (15-49 years), and about 10% were children (boys and girls) under 5 years old (Table 8 and 9). Both these demographic groups (women and children) are the target population of FTF nutrition-focused agricultural programs such as Cambodia HARVEST. The heads of the household in our sample on average had five to six years of schooling and were a little under 50 years of age. On average, a household owned about 2.7 ha of land, one to two tropical livestock equivalent units, and household assets worth US$3,200 in 2016—up from about $800 in 2012 (Table 9).

Tables 8 and 9 also describe the distribution of household by income sources—farming, off-farm activities, non-timber forest product (NTFP,) and other sources. Farm income came from sales of rice, livestock, vegetables, other crops, and fishing. Off-farm income sources included daily or occasional wage, salaries, self-employment, and pensions. NTFP income included only earnings from collecting and selling non-timber forest products. Other income sources included sale of assets, gifts, remittances, and other sources. In 2016, about 98% of households reported earning income from farming, 80% from non-farm income sources, 2-3% from NTFP, and about 48% from other sources. Over the previous four years, surprisingly, the percentage of households reporting incomes from non-farm and NTFP declined, but the percentage of households reporting other sources of income increased from about 30% to 48% (Tables 8 and 9). In both the years, the overall percentage of households reporting farm income was not significantly different between the two groups. However, income from other sources was significantly higher among the treatment group.

On several of these characteristics, the mean difference between the treatment and comparison households is statistically significant, such as household size, composition, ownership of livestock, types of assets, and income sources (Table 8 and 9). Also, the number of female-headed households increased from 2012 to 2016 in both the treatment and comparison villages. As can be seen from Tables 8 and 9, the female-headed households are characteristically different from male-headed households. For example, the size of the household is smaller for female-headed households than male-headed households, and the average age of the head of the household is significantly higher for female-headed households in both the treatment and comparison groups. Similarly, the ownership of land, assets, and income sources are different for female-headed households than male-headed households. This points to the need for controlling for the gender of the household head in any analysis focused on drawing causal inferences on project outcomes.

Our expectation was that, at least in the baseline, the sampled households would be similar in household characteristics, which would avoid the issue of placement and selection biases (at least those based on observable characteristics). However, this is not the case, as noted in Table 9. We thus needed to address this issue by using appropriate statistical/econometric technique in impact analysis. One way we addressed this issue was by including these characteristics as control variables to rule out attribution of any observed effect on the outcome on these inherent differences in characteristics of sampled households from the treatment and comparison groups.

5.3. Income Sources and Migration Patterns in the Study Area

To contextualize some of the demographic trends and household characteristics of the sampled households, it is important to understand the migration patterns and the changing income sources in the study area focused on by this evaluation. These can affect labor and capital availability for agricultural operations. Table 10 shows the pattern of outmigration for
sample 1 households by gender of the household head, age group, and region in the 5½-year project period. On average, 57% of the households from the treatment group had experienced outmigration of a member older than 15 years, which is much higher than the 46% of households experiencing outmigration from the comparison group. This pattern appeared to be higher among female-headed households than among the male-headed households (Table 10). In general, outmigration within the province involves people moving to urban areas. The rate of outmigration among female-headed households in the comparison group was higher than among male-headed households. For members 14 years or younger, outmigration showed a similar pattern between male- and female-headed households within the treatment and comparison groups. This pattern may affect the availability of labor in the agricultural sector and can potentially influence the uptake of Cambodia HARVEST-promoted technologies and practices.

Source: Cambodia HARVEST Endline Survey, 2016; n=number of observations.
Patterns of occupation changed from 2012 to 2016 among members of the 10 years or older age group (Table 11). Members reporting farming as the main occupation dropped from 58% in 2012 to 44% in 2016 among treatment households. A similar drop occurred in comparison households during the same period. There was a concomitant increase in the percentage of non-farm laborer and salaried employment from 2012 to 2016 in both the treatment and comparison groups. These changes reflect the shift from agriculture to non-farm sources of livelihood that occurs with structural transformation, and it has implications for both labor and capital availability for farming operation.

5.4. Tracking the Results along the Pathway from Interventions to Outputs and Outcomes

We used the 2016 endline survey (cross-sectional) data to report on how the households that were targeted by Cambodia HARVEST compared with the households that were not targeted by the project. We followed the conceptual framework presented in Figure 2 and specifically examine the 2016 survey data to track the results along the pathway corresponding to nodes outlined in yellow. We first looked at the participation rates of surveyed households in various activities and interventions conducted by Cambodia HARVEST or other organizations, and then reviewed the results on awareness and knowledge about some of the concepts/techniques promoted by Cambodia HARVEST and the uptake and adoption of these practices by the target group. We then examined the trend or change over time in some of the production, income, and nutrition-related outcomes noted in the red outlined nodes along the pathway in Figure 2.

5.4.1. Participation in Cambodia HARVEST Activities

In the 2016 endline survey, respondents were asked about their participation in the previous four years in any programs or activities of the type offered/promoted by Cambodia HARVEST in the study areas. These included hosting and/or participating in demonstration sites for rice, corn, aquaculture/fisheries, commercial horticulture, and home gardens programs. Questions were also asked about respondents’ participation in the business development training programs, forestry-related programs, nutrition field days, food security and nutrition groups, mobile kitchen program, and savings fund groups. The respondents were also asked about the main organizer of the activities/programs in which they participated and how many household members participated in each activity.

Table 12 describes the responses to these questions from all the treatment and comparison households, including the households added in 2016. The percentage of sampled households in the treatment villages that reported visiting or participating in these demonstration sites is much higher, ranging from 19% for corn demonstration to 73% for the home garden program. These farmers are referred to by Cambodia HARVEST as beneficiaries or participants and, as expected and in line with the project implementation strategy, the percentage of this type of farmer in our treatment sample is much higher than among the demonstration clients.

Participation by farmers in the treatment villages in other activities such as the business development program (BDM), forestry, nutrition, mobile kitchen, and savings group varies from 5% for BDM to 42% for nutrition field days. Again, the differential rates of participation in activities/interventions reflect the different scales at which these activities were conducted by Cambodia HARVEST (see Table 2) and possibly by other projects in the
study area. On average, 3.8 members from the sampled households in the treatment group and 1.4 members from the comparison group households participated in these types of programs and activities (Table 12).

n=number of observations; t-test: *** = p<0.01, **=p<0.05.
The percentages of program participating/visiting farmers in the comparison villages are significantly lower, indicating the absence of Cambodia HARVEST project activities in these villages, which is in line with the definition of *comparison group* for the impact evaluation. In fact, for some activities—such as aquaculture, forestry, BDM, food security and nutrition group, and savings fund group—none of the participant households in the comparison group reported Cambodia HARVEST as the main organizer of these projects. For other programs, the percentage of households indicating Cambodia HARVEST as the main organizer is very low, ranging from 1% to 6% (Table 12). Overall, 2% of program participating households in the comparison villages reported that Cambodia HARVEST was the main organizer.

Two observations on the results reported in Table 12 are worth noting for their implications on the impact analysis methodology and results. First, although the percentage of farmers participating in the listed interventions is significantly less in the comparison group than in the treatment group (as expected), there are still a significant number of farmers in the comparison villages who indicated either visiting or participating in activities/technical assistance programs of the type offered by Cambodia HARVEST (Table 12). This reflects potential contamination of project interventions in comparison villages that could bias the results of the impact evaluation. Second, the results point to the presence of interventions and programs offered by entities other than Cambodia HARVEST in both the treatment and comparison villages. For example, about 60% of sampled households from both these groups reported participating in at least one activity/intervention organized by the government or other NGOs in the previous 4 years (Table 12). This is potentially a source of a second type of contamination (i.e., presence of other programs in the study area), which can make attribution of effects to Cambodia HARVEST difficult to assess. The proportion of farmers reporting participation in programs other than Cambodia HARVEST is not significantly different between the treatment and comparison groups, which means that both the groups were equally affected by these other interventions and programs. These are considered exogenous effects in the program evaluation strategy and we address these types of contamination issues by controlling for households’ participation in interventions offered by other entities as explanatory variables in strategies 1 and 2. However, it is possible that these exogenous influences from other interventions may be qualitatively different and could potentially influence the outcomes differently across the treatment and comparison households. Unfortunately, there is no information on the content and type of these other interventions to control for these potential qualitative differences of other interventions in the study area.

5.4.2. Awareness and Knowledge of Cambodia HARVEST among the Main Respondents

Next on the pathway, we look at the influence of project interventions on farmers’ awareness, knowledge, understanding, perceptions, and attitudes about some of the concepts, ideas, and techniques promoted by Cambodia HARVEST (Figure 2). First, more than 98% of respondents from the treatment group (both male- and female-headed households) were aware of Cambodia HARVEST (Table 13). In comparison villages, about one out of three respondents had heard about Cambodia HARVEST, which may be due to the close proximity of the comparison villages to the treatment villages. The project had very good name recognition in the treatment villages and fairly good name recognition in comparison villages. Close to 30% of farmers in the study area also expressed general awareness about USAID. Name recognition for Fintrac was very low (2% to 33%), which is not surprising because the project was promoted as USAID/HARVEST or simply Cambodia HARVEST and not by the name of the main implementing partner.
The general awareness among respondents of terminologies associated with agricultural and natural resource management interventions—such as climate change, integrated pest management (IPM), and forest conservation—was statistically significantly higher among the respondents from the treatment group than those in the comparison villages, indicating a higher exposure to these ideas. Similarly, awareness about two examples of concepts/ideas promoted under the nutrition program—Bor Bor Kab (a nutritious porridge for young children) and the three food groups—was significantly higher among respondents from the treatment group than respondents from the comparison group. For example, 63% of farmers were aware of the three food groups, and 96% knew or had heard about Bor Bor Kab in the villages where Cambodia HARVEST was active, compared with 33% and 91%, respectively, in the non-intervention villages (Table 13).

As part of the general awareness-building campaign and training/capacity-building programs, Cambodia HARVEST developed several billboards and posters on the importance of forest conservation, fighting deforestation, the challenges of climate change, strategies for adaptation to climate change, environmental problems associated with chemical inputs, crop growth stages, and crop development, and the importance of a clean environment for livelihood and health. To gauge familiarity with these messages, respondents were shown copies of 10 such posters/billboards and asked if they had seen them before. The response among treatment groups (defined by sample 1) varied from 24% to 56% for various posters/billboards and was significantly higher than affirmative responses from respondents in the comparison group, which ranged from 19% to 46% (Table 14). For several of these posters/billboards, however, awareness among farmers in the comparison group was high, indicating the spillover effects of Cambodia HARVEST—the public nature of the billboards or the use of such posters by other projects/programs active in the comparison villages. Either way, these are positive effects of the project that can potentially underestimate the project effects or bias the results of the treatment effects.

a. Typically the respondent was the main decision maker in the household.

In Table 15, we look at the results of the 2016 survey on the general awareness of specific practices and technologies promoted by Cambodia HARVEST in the study area among the rice and horticulture farmers, and compare the awareness, past or current adoption, and current adoption of these practices between the treatment and comparison groups in sample 1. In general, the villages where Cambodia HARVEST was active had a significantly higher percentage of farmers who were aware of new and innovative practices in rice and vegetable...
production than the comparison villages where there was no Cambodia HARVEST. The difference in awareness about new practices between farmers from the treatment and comparison villages was generally higher among vegetable growers than among rice growers. Also, in general the awareness about new technologies and practices was much higher among male-headed than female-headed households. For example, among male vegetable growers in the treatment villages, 90%, 77% and 88% reported being aware of raised planting beds, plant spacing, and the practice of using plastic and straw mulch, respectively, compared with 65%, 47% and 50% of male farmers in the comparison villages. Across the two crop groups (rice and vegetables), the differences in the level of awareness between the two groups was more than double for techniques such as drip irrigation for vegetables, leaf color chart, improved rice varieties, live barriers, plastic cover nurseries, in-farm drainage, soluble fertilizers, integrated pest management (IPM), and biological control products (Table 15).

When asked if the farmer had ever used these new practices/technologies, the level of affirmative responses dropped for most of the rice technologies in both the treatment and comparison villages consistent with awareness, use and adoption rates found in other studies. Only for direct sowing of rice, row planting, use of short-duration improved rice varieties, and IPM practices were there at least 20% of rice farmers in the treatment group who reported ever using these techniques. The level of current use or adoption of these practices reported by the rice farmers further dropped to less than 5% for most technologies except direct sowing of rice (34% reported using that method at the time of the survey), short-duration improved rice varieties (16% reported currently using them) and IPM practices (10% reported currently adopting such a method). These findings are consistent with other studies. For example, a study conducted by Suvedi and Sarom (2017) reported that more than two-thirds of the Cambodian farmers planted traditional varieties except for dry-season, flood-recession and dry-season, lowland, irrigated rice. The current level of adoption reported by the treatment farmers was not statistically significantly different from the current level of adoption reported by farmers in the comparison villages. Only for row planting was the difference in the level of current adoption between the treatment and comparison farmers statistically significant, but the level of adoption reported was only 4% (Table 15).

The level of adoption and current adoption for most of the techniques and practices promoted among vegetable growers was significantly higher and more sustainable among the treatment villages than the levels for rice farming technologies (Table 15). A higher percentage of vegetable farmers reported adopting the new methods and techniques, and a significant percentage of farmers were still using the methods at the time of the survey. For example, 50% of vegetable farmers reported continuing to use the raised planting beds method, 44% were still using recommended plant spacing, 32% were using trellis netting, 28% were using mulch, and 23% were using compost. These findings are consistent with the results of the evaluation of commercial horticulture program of Cambodia HARVEST reported by Suvedi et al. (2017). They reported that demo clients were more interested in learning commercial horticulture technologies, given the access to technical support by the HARVEST program. A similar pattern was observed in their technology adoption. Similarly, younger farmers from the demo client group were more likely to adopt planting technologies than the training participant group.

---

16 This is not uncommon—the rate of awareness is always much higher than the rate of adoption of a technology. For example, Simtowe, Asfaw, and Abate (2016) found that of the 34% of farmers who were aware of an improved pigeon pea variety in Malawi, only 24% had ever used it, and only 14% were still planting it in the year the study was conducted. Similar patterns in gaps between exposure and use, and between use and continued adoption of technologies are reported by Floyd et al. (1999) for a wide range of technologies by farmers in Nepal, and Diagne (2006) for improved rice varieties in West Africa.

MHH=Male-headed HHs, FHH=Female-headed HHs; n=number of observation; t-test: **=p<0.01, *=p<0.05.
For both vegetables and rice, among both the treatment and comparison groups there was a
general decline in the percentage of farmers who adopted a new technology (once they
become aware of it) and those that continued to use it (sustainable adoption). The project
seems to have had some effect in increasing the level of awareness, uptake rate, and current
use among the treatment villages for several of the new technologies promoted by the project.
However, despite the project interventions, the challenges of sustainability remain the same
in villages where Cambodia HARVEST was active and in villages where it was not as
evident by the gap between awareness and uptake, and between uptake and current adoption.
It seems that only 50% of farmers who become aware of a new technology tried it or took it
up, and only 50% of those that tried it were still using the technology at the time of the
endline survey. Of those that were aware of a new practice but did not adopt it, the main
reasons given were non-availability of inputs (35%), labor constraints (29%), high cost
(16%), and lack of technical assistance (9%), which can provide a key to unlocking the
sustainability in different types of interventions.

5.4.3. Participation, Awareness, and Knowledge of Cambodia HARVEST among Women

As a nutrition-focused FTF project, Cambodia HARVEST also implemented many activities
and technical assistance programs targeted to women of childbearing age (15-49 years).
Empowering women with the knowledge and tools to make decisions that affect the way
time, money and other resources are spent within the household, the types of foods grown
and consumed by the household, the way home cleanliness is maintained, types of foods
served to children, and the ways in which food is safely prepared for the family are seen as
important pathways through which the project can ultimately improve household food
security and nutrition outcomes, which is the ultimate goal of the FTF Initiative under which
Cambodia HARVEST was funded. Thus, we track the results of Cambodia HARVEST
project interventions along the pathway by presenting the results of the participation,
awareness, knowledge, and adoption of some of the nutrition, hygiene, and food preparation
practices promoted by the project to women aged 15-49 who are mothers, caregivers, or the
main food preparers in the households surveyed.

Tables 16 and 17 present the comparison of some of these indicators of participation,
awareness, and adoption measures between women respondents in the treatment and the
comparison groups based on the endline survey data collected in 2016. More than 80% of
women in sample 1 that were interviewed in Cambodia HARVEST villages had heard about
Cambodia HARVEST, 36% had attended some kind of nutrition-related training program in
the previous four years, 29% had participated in mobile kitchen, cooking demonstration, food
safety, and hygiene-related training activities, and 47% had participated in training on home
and school gardening, planting fruit trees, postharvest handling, and storage (Table 16).
About 40% of women reported having received in the previous four years seedlings of
Moringa, a tree with many nutritional and health benefits, promoted by the project. Fourteen
percent of women in treatment villages reported that they were currently or in the past four
years had been members of a food security and nutrition group, and 30% reported being
members (currently or in the past four years) of a savings fund group (Table 16). On all these
measures, the level of project awareness and participation was significantly higher among
women in treatment villages than women in the comparison villages, as expected (Table 16).
The positive levels of awareness about Cambodia HARVEST and participation in some of
these programs reported by women in the comparison group indicate either spillover effects
of the Cambodia HARVEST activities or the presence of other government organizations or
NGOs promoting similar programs in the comparison villages.
The women were also shown five posters related to concepts of hygiene and nutrition that were developed and used by Cambodia HARVEST in various training programs to gauge their familiarity with these visual aids. As shown in Table 16, there was a high level of awareness and familiarity with these posters among both the Cambodia HARVEST intervention villages and the comparison villages. In the treatment group, 65% to 84% of women reported having seen these posters before, and 55% to 71% of women in the comparison group reported having seen the sample posters (Table 16). The level of familiarity with these posters was much higher among women in the treatment group than among women in the comparison group, as expected.

Table 17 reports the comparison of knowledge and adoption of practices promoted by the project among women in the treatment and comparison groups, especially those that identified themselves as caregivers of a child or the main food preparer in the households surveyed. On some of the hand washing practices, there were significantly more women reporting the correct method and timing of hand washing in the treatment group than in the

The women in the treatment group also reported having a higher level of knowledge than women in the comparison group about some of the food consumption practices for children and adults and of the concept of three food groups. There was also a high prevalence of women owning or managing a home garden plot (69%), making Bor Bor (enriched porridge) for children (35%), and serving at least one of the items from each of the three food groups in all the meals (72%) (Table 17). On all these measures reported in Tables 16 and 17, women in the Cambodia HARVEST intervention villages had a higher level of awareness, knowledge, and practice related to good hygiene and the importance of nutritional foods than women in villages where Cambodia HARVEST did not intervene. However, whether this higher level of knowledge and practice translates into better quality of food consumption (as measured by dietary diversity), adoption of good infant and young child feeding practices, and improvements in nutritional outcomes (as reflected in stunting, wasting, and underweight among children under 5) is yet to be seen. This is the topic of investigation for the impact analysis presented in Section 6. Here it is worth noting the qualitative study by Chung, Lopez, and Bora (2017) that examined some of the recommended complementary and transitional feeding practices promoted by Cambodia HARVEST. In this study, the authors focused on two child feeding practices promoted by Cambodia HARVEST: the use of enriched porridge and the inclusion of the three food groups (TFG) in child meals. The main finding of that study was that there was little evidence that households were using enriched porridge. It was also reported that the TFG was not applied in an intentional way by caretakers. Young children were more likely to receive TFG when meals for the rest of the family included dishes with the TFG.

5.4.4. Comparison of Outcomes before and after and between Treatment and Comparison Villages

It is expected that awareness, knowledge, and adoption of practices promoted by the project would lead to improvement in productivity, income, expenditure, consumption, quality of dietary intake, and ultimately in nutritional outcomes as measured by stunting, wasting, and underweight among children and underweight among women of reproductive age (15-49 years). These are some of the indicators of outcomes and impacts expected to be influenced by the project as depicted in Figure 2. We thus track the results and outcomes by examining the changes that have taken place—or not—in some of these indicators along the pathway by comparing the estimated values in 2012 with those in 2016 between the treatment and comparison households.

Table 18 shows changes in the following outcome indicators along the pathway for treatment and comparison groups by the gender of the head of the household: crop productivity, value of production, crop sales, crop income (as measured by net income per household)\(^\text{17}\), per capita expenditures, poverty, hunger (an indicator of food security), dietary diversity among women and children, prevalence of underweight among women, and prevalence of stunting, wasting, and underweight among children younger than 5 years.

Table 18 illustrates the trends in these indicators for sample 1 households from the beginning of Cambodia HARVEST (2012) to the end of the project (2016). Average rice yield for farmers in the treatment group was higher than average yields in the comparison group in both those years, though both groups showed an increasing trend from 2012 to 2016.

\(^\text{17}\) Value indicators for all crops are reported in real 2012 Riels. Values for 2016 were adjusted using consumer price index to derive values in 2012-equivalent Riels.

Source: Cambodia HARVEST Impact Evaluation Surveys, 2012 and 2016. Indicators are reported at household level; n=number of observation; t-test: **= p<0.01, *=p<0.05.
Among the treatment households, rice yield increased from 2.1 tons/ha per household in 2012 to 2.3 tons/ha per household in 2016. Average rice yields in the comparison group increased from 1.8 tons/ha to 2.1 tons/ha during the same period. Rice net income per household also increased from 2.5 million Riels to 4.6 million Riels (in 2012 Riels) among treatment households during the 2012-2016 period, and increased from 1.9 to 4.1 million Riels among comparison households. Not surprisingly, male-headed households experienced higher levels of outcomes on all counts of productivity, sales, and crop income than female-headed households.

We also track and report the area, value of production, sales, and net income for vegetable crops, given the focus of Cambodia HARVEST on promoting home gardens and horticulture value chains. As expected, value of production and sales of vegetable crops significantly increased during the project period for the treatment group. Total value of vegetable sales per household doubled among treatment households; the incremental rate among comparison households was lower than the rate among the treatment households (Table 18). However, the net household income from vegetable production declined significantly for both the treatment and comparison groups from 2012 to 2016. Only the female-headed households in the comparison group saw an increase and a positive level of net income from vegetable production (Table 18).

For fish production, the number of observations is not adequate to do mean comparisons by the gender of the head of the household. For the overall sample, the results suggest a positive trend in the total quantity of fish production, value of production, and net income in the treatment group. However, the sample size for the comparison group (only nine observations) is too low to conduct any impact analysis for this outcome indicator in the subsequent sections. Although we are not able to explore this further in this study because of small sample size, it should be noted that the case study conducted by Richardson et al. (2017) points to potential for aquaculture technology to contribute to household income, food security, and nutrition. That study suggests that adoption of small-scale aquaculture systems in rural Cambodia as promoted by Cambodia HARVEST was limited by several factors, including access to water, prices of commercial fish feed, selling price of fish in markets, and concerns about profitability. Access to fingerlings was identified as a major barrier. Limited provision of extension services, market access, land access, and off-farm employment opportunities were identified as other barriers to effective development of community fisheries.

Next we track the trends in some of the FTF indicators along the impact pathway that the project is hypothesized to influence through its income-focused value chain programs and nutrition-focused technical assistance programs: the prevalence of poverty, hunger, and malnutrition among the targeted population. Table 18 shows the changes in per capita expenditures and the prevalence of poverty and hunger among treatment and comparison households from 2012 to 2016. The prevalence of poverty was measured as the percentage of people living on less than US$1.25 a day measured in 2005 US$ purchasing power parity (PPP). Among the villages targeted for Cambodia HARVEST interventions in 2012-2013, the poverty rate significantly had decreased from 10% to 4% in the four years leading up to the endline survey. A similar pattern is also observed in the comparison group, with the prevalence of poverty observed to have decreased from 13% to 5% between 2012 and 2016. The 6% to 8% drop in the poverty rate observed in the impact evaluation study area in both the treatment and the comparison villages is of a much larger magnitude than the roughly 4% reduction in the poverty rate from 2009 to 2015 reported for the entire zone of influence (i.e., the four targeted provinces) in Cambodia by the 2015 Interim Assessment Report (Social Impact 2015).
Annual per capita expenditure on food and non-food items (excluding housing) increased among both treatment and comparison groups between 2012 and 2016, but the rate of increment appeared to be higher among treatment households (US$548 to US$618) than in the comparison group (US$522 to US$578). The prevalence of households with moderate to severe hunger (defined as a score of 2 or higher on the 0-6 household hunger scale) differed between treatment and comparison groups. The treatment group had a much lower percentage of households with hunger in 2012, but the comparison group improved at the endline, reducing the gap between the two groups during the project period. However, in both the groups, the prevalence of hunger was extremely low in the study area (less than 1%), and the magnitude of changes in the treatment and comparison groups is insignificant and inconsequential. We want to point out that the estimated prevalence of hunger among our study population in 2016 (~0.2-0.3%) is significantly lower than the estimated prevalence of hunger in the ZOI a year earlier (8.6%) as reported in the Interim Assessment Report (Social Impact 2015). This large discrepancy in the prevalence of hunger could be either a reflection of the different study populations (much narrower geographic focus of this impact evaluation study area versus the entire ZOI) or the different time frames over the 12-month period captured in the two surveys (i.e., the season/month the survey was undertaken), or it could be the year effect (i.e., weather variability), which could have reduced food availability in 2015 (due to drought) more than in 2016.

Table 18 also presents the status of dietary diversity and prevalence of underweight women of childbearing age (15-49) among the treatment and comparison households in 2012 and 2016. Women’s dietary diversity score (WDDS) captures how many out of nine food groups an individual consumed in the past 24 hours: grains, roots, and tubers; legumes and nuts; dairy products; organ meat; eggs; flesh food and small animal protein; vitamin A-rich dark green leafy vegetables; other vitamin A-rich vegetables and fruits (including orange-fleshed sweet potatoes); and other fruits and vegetables. The mean number of food groups consumed by women is tabulated by averaging the number of food groups consumed across all women of reproductive age in the sample with data available on dietary diversity.

If we compare the number of food groups consumed by women (Table 18), there appears to be no difference between treatment and comparison groups in the baseline and endline periods. The mean number of food groups consumed by women is similar across the two groups (about 4.5), with a statistically significant but small decline observed between 2012 and 2016 for the treatment group. This estimated mean number of food groups consumed by women in the study area is similar to the mean number of food groups consumed by women (4.3) in the zone of influence in the Interim Assessment Report (Social Impact 2015). The prevalence of underweight women in both treatment and comparison groups went down over the project period, but the percentage change from 2012 to 2016 was relatively smaller in the treatment group than in the comparison group. During the project time frame, the percentage of underweight women in the treatment group was almost constant, whereas it declined by three percentage points (i.e., from 16% to 13%) in the comparison group from 2012 to 2016. A perplexing fact to note is that the prevalence of underweight women found in the study area in 2016 (13% to 15%) is statistically significantly higher than the prevalence of underweight women (12%) estimated for the entire ZOI in 2015.18

Table 18 also shows the minimum acceptable diet and dietary diversity for children and changes from 2012 to 2016 in three anthropometric measurements of undernutrition among

---

18 One reason for this difference could be the rural focus of this evaluation, whereas the 2015 survey included both rural and urban population in the ZOI.
children under 5 years: stunting (based on height-for-age z-scores), wasting (based on weight-for-height z-scores) and underweight (based on weight-for-age z-scores). It also shows the percentage of children 6-23 months of age in the Cambodia HARVEST intervention and the comparison groups receiving a minimum acceptable diet. Stunting is an indicator of linear growth retardation, most often due to prolonged exposure to an inadequate diet and poor health. Wasting is an indicator of acute malnutrition. Children with wasting have extremely low weight for their height and have a much greater risk of mortality than children without wasting. Underweight is a weight-for-age measurement and a reflection of acute and/or chronic undernutrition because it is a composite index of weight-for-height and height-for-age. Weight-for-age (i.e., underweight) is an overall indicator of a population’s nutritional health (WHO 2006). Reducing the prevalence of these conditions among children, particularly from birth to 23 months (i.e., the first 1000-day window of opportunity) is important because height and weight growth deficits accrued early in life are associated with cognitive impairments, poor educational performance, and decreased work productivity among adults. These are, therefore, considered to be important indicators for tracking the progress of the Feed the Future initiative across countries and are expected to be influenced by nutrition-focused development investments in the ZOI.

The results indicate the prevalence of stunting, wasting, and underweight among children younger than 5 to be, respectively, in the range of 30%, 10%, and 20%, respectively, among the treatment group in 2016. At least for the treatment group, the prevalence of these three indicators of malnutrition declined between 2012 and 2016. The results are, however, mixed for children in the comparison group. Overall, across the treatment villages, 44% of all children under 5 were stunted in 2012. This percentage was significantly reduced to 32% in 2016. Among comparison households, there was a similar reduction in the percentage of stunted children during this period. Percentage of wasted children also went down in the treatment group (from 11% to 9%), but it increased in the comparison group (9% to 14%) between 2012 and 2016. Prevalence of underweight children in 2012 differed between the two groups. Across treatment households, 28% of children were underweight; this went down to 18% in 2016. A similar pattern was observed in the comparison group during the same period. The estimated rates of stunting, wasting, and underweight among children younger than 5 in the study area were similar in magnitude for the ZOI—i.e., 34% stunting, 10% wasting and 25% underweight (Social Impact 2015).

The percentage of children ages 6-23 months receiving a minimum acceptable diet fell from 33% to 32% among treatment households but increased from 35% to 37% among comparison households from 2012 to 2016. Compared with estimates for the ZOI, the percentage of children 6 to 23 months of age receiving a minimum acceptable diet in 2016 is about 10 percentage points higher in the study area than the estimated percentage in 2015 by the Interim Assessment Report for the entire ZOI (Social Impact 2015). Also, not surprisingly, male-headed households are better off than female-headed households on all counts of poverty, expenditure, dietary diversity, and nutrition outcomes. This reinforces the importance of controlling for this confounding factor in the impact analysis to assess the causal effects of Cambodia HARVEST.

Another potential confounding factor in influencing the outcome indicators could be the location. We thus compare the mean values of these outcome indicators by treatment and comparison groups across the four provinces. Results are presented in Table 19 for the crop-specific outcomes and in Tables 20 and 21 for downstream effects on poverty, expenditure, dietary diversity, and nutritional outcomes for women and children younger than 5 years.
The four provinces vary significantly in the relative values for area devoted, production per household, value of production, and sales per household across the three focused commodities (Table 19). For rice, the size and scale of area and production are much smaller in Siem Reap and Kampong Thom than in Battambang and Pursat. Similarly, the values for productivity indicators (e.g., yield, sales, net crop income) are smaller for Siem Reap and Kampong Thom than for the other two provinces. For rice, except for sales, most provinces saw a significant increase in the values of these indicators from 2012 to 2016.

In the case of vegetables, the area, production, value, and sales are much higher in Siem Reap compared with other provinces (Table 19). In trend over time, Siem Reap is the only province that experienced a significant increase in the value of production and sales from 2012 to 2016. Similar positive and significant trends are also observed in Siem Reap (but not in other provinces) for total quantity of fish production and value of production (Table 19). The four targeted provinces also differ in the prevalence of poverty (Table 20). The percentage of people living on under US$1.25 per day was highest in Siem Reap (11% in the treatment group and 15% in the comparison group) in 2012; but that province saw the steepest decline in poverty rate in the treatment group over the four years (Table 20). The same relative difference and trends are observed across the four provinces for per capita expenditures by the treatment group. The only exception is Battambang, where the increase in per capita expenditures from 2012 to 2016 was not significant in either the treatment or the control group. The prevalence of hunger is relatively low across all the provinces and did not change significantly over the four years from 2012 to 2016 (Table 20).

Table 21 shows the outcomes on women’s dietary diversity, minimum acceptable diet for children, and prevalence of underweight, stunting, and wasting among the targeted population using sample 1 as the definition of treatment group. Battambang and Kampong Thom saw a statistically significant but small decline in the women dietary diversity score from 2012 to 2016, but no significant change in the prevalence of underweight women occurred in all four provinces. All four provinces also saw a decline in the prevalence of stunting and underweight children in both the treatment and comparison groups. However, the comparison groups in Kampong Thom, Pursat, and Siem Reap all witnessed an increase in the prevalence of wasted children from 2012 to 2016, although this was not statistically significant. The indicators on children’s dietary diversity and adequacy show more or less similar status and positive trends for the treatment and comparison groups across the four provinces. The exception is with the exclusively breast-fed children under 6 months of age. In general, the percentage of children exclusively breast-fed in the treatment group declined in Battambang, Pursat, and Siem Reap from 2012 to 2016. But over the same period, the value for this indicator either remained the same or increased for the comparison group. Whether this reflects the changing role of women in the farming operations in the treatment group triggered by Cambodia HARVEST activities or it is due to some other changing social or cultural practices needs further investigation.
Table 19. Summary of Agricultural Indicators along the Impact Pathway for Households in Sample 1 by Province (Comparison in Trend from 2012 to 2016)

* t-test: **= p<0.01, *=p<0.05.
In summary, the results presented in Tables 18-21 indicate that, on all the counts of productivity, crop income, expenditures, poverty, hunger, dietary diversity, and indicators of malnutrition, sampled households from the Cambodia HARVEST-targeted villages saw a significant improvement from the levels observed in 2012 (baseline of the project) to 2016 (endline of the project). These are quite encouraging results. However, similar improvements in these indicators were also observed in non-treatment villages. The fact that there were other donor and government programs active in the comparison villages could be a plausible explanation of this outcome.

In light of these findings, the purpose of this impact evaluation is to assess the extent to which these changes observed among the treated households can be attributed to Cambodia HARVEST interventions (i.e., to rule out other confounding factors that may have caused these changes). This question is the focus of the impact analysis presented in the following section. The results of this descriptive analysis point to some significant differences in the level and trend of the outcome indicators by the gender of the head of the household and across provinces. Thus, all the analyses that address these questions are presented in the next section not only for the overall sample but also disaggregated by provinces and the gender of the household head.
6. RESULTS: IMPACT ANALYSIS

6.1. PSM-DiD Methodology Results

We used the PSM-DiD methodology outlined in Section 4 to estimate the average treatment effect on the treated (sample 1) and the intent to treat treatment (ITT) effect (sample 2) of Cambodia HARVEST in the study area. This methodology compares the matched samples of households from the treatment and comparison groups (matched on the basis of pretreatment characteristics) and then uses the pre- and post-treatment survey data from the same households across the treatment and comparison groups to assess whether the mean difference in the change in outcome variable in the two time periods is statistically significantly different between the treatment and comparison groups after we take into account other confounding factors that could also potentially affect the change in outcomes. This analysis includes all the observations from the two analytical samples defined in Table 6, irrespective of which value chain or other Cambodia HARVEST activities each household participated in. It should be noted that the estimated impact based on sample 2 (ITT) is conservative because of dilution due to some households not graduating as Cambodia HARVEST clients. This type of effect estimation Sample 1s also more prone to type 2 errors (false negatives).

We estimated the impact of Cambodia HARVEST for the following outcome indicators along the pathway conceptualized in Figure 2: crop yields per hectare, volume, value, sales, and net income per household for rice and vegetables, expenditure per capita, poverty status, women’s dietary diversity score, prevalence of underweight women, minimum acceptable diet for children younger than 5 years, and prevalence of stunting, wasting, and underweight among children under 5 years.

We present in Tables 22-25 the summary results of the PSM-DiD regression models for the agricultural outcome variables noted above (Tables 22 and 24) plus some downstream outcome indicators along the impact pathway (Tables 23 and 25). For the outcomes based on anthropometrics data, results are presented for both the status outcome (binary variable) as well as the z-scores (continuous variable). For each outcome indicator, we include the results of the PSM-DiD model for both the samples in the same table (i.e., sample 1 and 2). For robustness check, we estimated the models on the basis of two propensity score matching methods – nearest neighbor and kernel, as explained in Section 4. For brevity, however, only the results of the nearest neighbor matching method using the propensity scores as a control variable are reported in these tables. For all indicators, the model is estimated for the overall sample 1 and sample 2, as well as disaggregated samples for each provinces and the gender of the head of the household. Results based on the correlated random effects (CRE) estimator are presented in Tables 22 and 23, and those based on the household fixed effects (FE) estimator are presented in Tables 24 and 25. Full results of these regression models are included in Annex 4 for CRE and in Annex 5 for FE.

Values reported in Tables 22-25 are the coefficients for the DiD variable (i.e., δ in equation 3), which are the Cambodia HARVEST program effects net of the time trend (i.e., changes between 2012 to 2016 due to time varying factors), differences between the treatment and comparison groups, and observed differences among households within the sample (i.e., other covariates included in the regression). For example, the results indicate that, keeping all things constant, the program effect on rice yield was -0.09 t/ha, ranging from -0.02 t/ha among female-headed households to -0.12 t/ha among male-headed households. Across provinces, the program effect was negative and statistically significant in Pursat (-0.27 t/ha) to positive but not statistically significant in Siem Reap (0.09 t/ha) (Table 22).

*p < 0.05, ** p < 0.01. Standard errors are in parentheses. Standard errors are clustered at the village level.

Note: PSM-DiD Sample 1s based on nearest neighbor-4 matching method. Sample 1 uses stringent definition of treatment households that excludes households with all program dropout members. Sample 2 includes households with members that started as clients but later became inactive.

a. Model cannot be estimated because of few observations or model failed to converge.

b. All the values in Riels are adjusted for inflation and reported in real terms in 2012 Riels.
Similar size and direction of effects are observed for wet- and dry-season rice yields across provinces, for the overall sample, and for male- and female-headed households. The program effect on total rice production, value of production, sales, and net income per household is positive for the overall sample.

Similarly, the effect on the value of vegetable production and sales is positive, but the effect on vegetable net income is negative (-0.14 million Riels/household). But none of these effects are statistically significantly different from zero for the overall sample. These results are consistent between the two analytical samples used to define the treatment group and for both the CRE and FE model estimations (Tables 23 and 25). The only exception is the significant program effect on overall rice yield and wet-season rice yield in the FE model for sample 2. Using the FE model and the larger sample that includes 185 households that were enrolled as clients but later became inactive gives an estimate of the program effect to be -0.13 t/ha (Table 24). Most of these negative effects are associated with male-headed households (-0.17 t/ha) and with the Pursat Province (-0.30 t/ha).

In differential program effects by the type of household or its location, we found few statistically significant robust effects on agricultural outcomes in addition to the effects on rice yield noted above. One such effect of Cambodia HARVEST is the positive effect of increasing the value of vegetable production by female-headed household by 0.16 million Riels. In three out of four sample by model combinations, this effect was found to be statistically significant at p<0.05. Another robust but negative effect observed across both sample 1 and 2 and in CRE and FE models is the program effect on vegetable net income in Kampong Thom and Pursat provinces. In these two provinces, Cambodia HARVEST client households experienced a decrease in net vegetable income of 0.20 million to 0.30 million Riels compared with households in the comparison group (Tables 22 and 24).

Moving down the pathway, we estimate that the program increased per capita annual expenditures by US$3 to $4 and reduced the percentage of people living on less than US$1.25/day by 0.2%. However, effects are negligible and weren’t found to be statistically significant effects of program participation. Also, the results across the various models and sample strategies used for robustness check found no significant effects of the program—in either magnitude or in the statistical sense—on the indicators of dietary diversity among women and children and nutritional outcomes for women as measured by percentage of women who are underweight.

The only nutritional indicators for which the program showed a significant effect, at least for the CRE models, are the prevalence of wasting and underweight among children under 5 years of age. Results indicate that the program contributed to about a 9% reduction in wasted children. On the other hand, the program effect is opposite for underweight children when the sample includes non-active client households (i.e., sample 2). The program is estimated to increase the prevalence of underweight children by about 9% in sample 2 (Table 23). Both these positive and negative effects on child nutrition observed under the CRE models are not present, however, when the analysis is based on household FE estimator and the time constant variables are excluded in the regression (Table 25). Interestingly, the program effects are not found to be statistically significant across provinces and gender of the household head for any of the downstream indicators across both the CRE and FE models and both the analytical samples of the households.

\(^a\) indicates that model cannot be estimated because of few observations or model failed to converge.
\(^b\) Marginal effects are reported.
\(^c\) Based on Negative Binomial CRE Model.

The full results presented in Annex 4 and 5 show several interesting and expected associations between the outcome variables and several covariates included in the model to control for sample differences. For example, rice production (value and quantity) and net income are positively associated with the household head being a male and wealthy households (as indicated by value of assets and land holding) and negatively associated with cost of inputs, owning tractor, and household engaged in growing dry-season rice. At least in the CRE models, rice production and net income are also positively associated with the number of years the HH participated in the Cambodia HARVEST interventions. Rice productivity (as measured by yield) is negatively associated with operated area but positively with input use (as represented by input cost variable) and assets owned (indicator of HH wealth) (Annex 4 and 5).

For vegetables, the only statistically significant correlations are with the input cost (positive for value of production and sales but negative for net vegetable income) (Annex 4 and 5). For the downstream impacts on household welfare, the results also indicate that household expenditures are significantly lower as the household size increases but significantly higher as the percentage of household heads who attended school goes up. Household expenditures are also positively associated with ownership of a cell phone and value of assets.

At the individual level of outcomes, the women’s dietary diversity was found to be positively correlated with the amount of money spent on food consumption per person per day. The number of food groups a woman ate in the past 24 hours was also found to be higher if she was the caretaker of a child in the household. Surprisingly, the women’s dietary diversity scores were negatively correlated with a household’s participation in the HARVEST program.
as a client in home garden and rice value chains. No statistically significant correlations were
detected between child-level nutritional indicators and the child- or household-level
characteristics. Perhaps this could be due to the smaller sample size for some of these
indicators in restricted samples 1 and 2 used in this analyses.

6.2. Discussion of PSM-DiD Results

The analysis presented in this section failed to detect statistically significant and robust
results of Cambodia HARVEST on most of the key outcome variables as measured by the
intent to treat treatment effects (sample 2) or the average treatment effects (sample 1). In
other words, comparing the before and after intervention data between the treatment and
comparison villages and controlling for potential confounding factors reveal no statistically
significant effect of the program in changing the average values of some key indicators across
all the sample households included in the treatment and comparison villages. These results
are consistent across provinces and male- and female- headed households.

The reasons for being unable to detect any program effect (i.e., coefficients significantly
different from zero) across the various model specifications could be threefold. One plausible
reason could be that the sample size was not large enough to detect the treatment effect. This
is especially the case for sample 1, which is based on 1609 household observations, which is
almost 500 observations less than the initial sample size. This represents a significant loss of
statistical power in detecting smaller treatment effects. Although 179 households were lost to
sample attrition (i.e., households no more living in the same village), a significantly large
number of households from the treatment villages (312) were dropped from the analysis
because either they did not participate or had become inactive clients in Cambodia
HARVEST, even though they were selected to receive the interventions at the time of the
sample selection in 2012. Both these types of sample attrition problems represent practical
challenges to conducting rigorous impact evaluations of development projects that require
panel data analysis. Unlike clinical trials, in which people assigned to a treatment receive the
treatment, in development interventions such as those promoted by Cambodia HARVEST,
there is no guarantee that people selected for a treatment will indeed be treated. The high rate
of non-compliance that was observed among the treatment group in this study necessitated
dropping both the non-participating and inactive households from the analyses to estimate the
average treatment effect on the treated households (sample 1) or only dropping the non-
participating households to estimate the intent to treat treatment effect (sample 2). However,
the reduced sample size under both these strategies lowered the statistical power of the
analysis and thus lowered the ability to detect the effect sizes significantly different from
zero.

A second potential reason could be the positive spillover effects of Cambodia HARVEST or
other similar programs in the comparison villages. As noted in the descriptive analysis, there
were other programs organized by NGOs, government organizations or other donors that
were active in the study areas, and many in the comparison villages reported having received
similar interventions in the past four years. Moreover, the average distance between a
comparison village and the closest Cambodia HARVEST intervention village was only 1.4
km. This close proximity of comparison villages to a treatment village also implies a high
probability of messages, techniques, practices, and inputs promoted by Cambodia HARVEST
reaching and influencing farmers’ behavior in the comparison villages nearby. Given these
two sources of potential contamination—the spillover effects from Cambodia HARVEST and
other similar programs—it is difficult to defend the comparison group for this evaluation as a
true control group. This is another practical challenge of conducting rigorous impact
evaluations of development projects like Cambodia HARVEST, where households from the comparison group can self-select to receiving similar interventions. This contamination of the comparison villages threatens the integrity of the evaluation design, as is likely the case in this study.

A third plausible reason for inability to detect any significant effects could be the fact that the program was not the cause of the net changes observed over time and between the treatment and comparison groups for the indicators evaluated. In other words, the observed positive changes in the outcome indicators observed in the treatment group before and after Cambodia HARVEST were not caused by Cambodia HARVEST alone but by some other factors that may or may not include the Cambodia HARVEST project as one of the change agents. The results do not indicate is that the project was the cause of any negative effects on the beneficiaries’ production, income, poverty, and other welfare indicators. The failure to detect statistically significant program effect implies that the study is inconclusive, (about the cause of the observed change in outcomes, rather than a proof that the project was ineffective.
7. CONCLUSION AND EMERGING LESSONS

As a flagship project under the Feed the Future initiative, Cambodia HARVEST aimed to contribute toward the two FTF objectives of agricultural sector growth and improved nutritional status for women and children by integrating nutrition as one of the cross-cutting components in its agriculture-focused interventions. Cambodia HARVEST adopted a comprehensive strategy to influence individual and farm household behavior change, adoption of practices, and women’s empowerment, which can lead to agricultural growth (as reflected in increased productivity, diversification, input availability, sales of produce, and storability, safety, and quality of food), increased production and income, and ultimately to improved food security and nutrition outcomes through increased expenditures and adequate and diverse food intake.

With this income-focused agriculture-nutrition linkage framework as a backdrop, this study was designed to assess project outcome status on some key indicators along the impact pathway and to evaluate the impacts of project interventions using rigorous impact evaluation methodologies. Through these two sets of analytical approaches (descriptive and rigorous impact analysis), the study aimed to test the following hypothesis: farm households that participated in or received Cambodia HARVEST interventions (i.e., technical assistance, extension services, training, field demonstrations, etc.) would have greater availability of food as measured by total production (quantity and value) (food production pathway); increased income from production as measured by net income (from rice, vegetables and fish) and total expenditures (income pathway); and more diverse diets and improved nutritional outcomes for children and women (a combination of production, income, and women’s empowerment pathways).

The descriptive analysis points to the project’s success in influencing several targeted outputs and outcomes along the impact pathway. The general awareness and knowledge about concepts, terminologies and practices promoted by the project was significantly higher among households from Cambodia HARVEST-targeted villages than in the comparison villages where Cambodia HARVEST did not intervene. The women in the treatment group also reported having a higher level of knowledge than women in the comparison group about some of the food consumption practices for children and adults, the concept of three food groups, and practices related to good hygiene. Although these are not surprising findings, they confirm this immediate result of Cambodia HARVEST as testified by the farmer survey.

Beyond awareness and knowledge, the respondents in Cambodia HARVEST intervention villages also reported a high prevalence of uptake and adoption of good agricultural production and nutrition practices promoted by the project. For example, a significantly higher percentage of women in the treatment villages reported owning or managing a home garden plot, making borbor (enriched porridge) for their children, and serving at least one of the items from each of the three food groups in all meals compared with women in villages where Cambodia HARVEST was not implemented. Also, a significantly higher percentage of farmers in treatment villages than farmers in comparison villages reported having adopted some of the improved technologies and practices promoted by the project for rice, such as direct seeding, row planting, and use of drought-resistant varieties, and for vegetables such as raised planting beds, plant spacing, trellis netting, plastic and straw mulch, use of compost, etc. So on these subintermediate result indicators of uptake and adoption—which are necessary conditions for achieving higher level impacts on productivity, income, and nutrition—Cambodia HARVEST villages did better than comparison villages, as reflected in a significantly higher percentage of farmers in HARVEST villages reporting having used or
tried some of the practices and techniques aimed at enhancing both food production and consumption.

Beyond adoption and uptake of improved practices, the results of descriptive analysis also indicate that on all the counts of productivity, crop income, expenditures, poverty, hunger, dietary diversity, and indicators of malnutrition, sampled households from the Cambodia HARVEST-targeted villages saw a significant improvement from the levels observed in 2012 (start of the project) to 2016 (end of the project), implying that Cambodia HARVEST beneficiaries were better off in 2016 than in 2012. The impact analysis was intended to determine whether these improvements can be attributed to Cambodia HARVEST interventions (i.e., to rule out other confounding factors that may have caused these changes). We used the restricted sample of treatment households that had participated as clients in the rice, home garden, and aquaculture value chain activities of Cambodia HARVEST to estimate the average treatment effects and the intent to treat treatment effects based on the PSM-DiD CRE and FE estimation models. We found that between 2012 and 2016, outcomes for households in the comparison group had improved as much as those of project beneficiaries. The analyses thus failed to detect any robust and statistically significant differences between the levels of improvements in the two groups. In other words, comparing the before and after intervention data between the treatment and comparison villages and controlling for potential confounding factors showed no statistically significant positive effect of the program in changing the average values of some key indicators, such as gross income, total expenditures, poverty status, dietary diversity, and nutritional outcomes as reflected in stunting, wasting, and underweight of children under 5 years of age, and underweight among women of childbearing age. However, because other donors and government programs were active in the study area in both treatment and comparison villages, and treatment and comparison villages were an average of 1.4 km apart increasing the chances for spillover, this study cannot arrive at any conclusions about the relative effectiveness of Cambodia HARVEST, other donor programs, or no interventions.

We offer the following thoughts on some of the limitations of this study and lessons learned. Some of these limitations reinforce the potential reasons mentioned above for the overall inconclusive results.

### 7.1. Limitations of Sampling Methodology

Several features of the sampling methodology used for impact evaluation were less than ideal and did not conform to the impact evaluation design proposed for this study (Suvedi 2012). First, the actual sample size selected for the study deviated from the proposed impact evaluation design. For example, the proposed sample size based on power calculation was proposed to be 2,700 households, with treatment villages to be selected from Phase I and Phase II targeted villages. However, because the list of clients for Phase II were not finalized at the time of the baseline survey, the actual sample size was reduced to 2,100 households, which lowered the statistical power of the impact evaluation design to detect small effects. At the time of the endline survey, we also discovered that one of the comparison villages was intervened by HARVEST, which necessitated classifying it as a treatment village. That further reduced the sample size for the comparison group and the statistical power of the analyses.

Second, the actual sample of households used for the impact analysis presented in this paper was further reduced because of sample attrition (from baseline to endline survey) and non-conformity issues. For example, several hundred households that were selected from the list
of clients targeted to receive direct Cambodia HARVEST technical assistance were found (after the endline survey) to have either not participated in the program or eventually dropped out. As a result, the final sample size of panel households was 1,609, i.e., 1,088 for treatment group and 521 for the comparison group. This smaller sample size further reduced the statistical power of the analysis to detect the program effect.

Third, the comparison villages selected for the evaluation were geographically located in close proximity to the treatment villages. When the treatment and comparison villages were selected in 2012 for the baseline survey, the average distance between a comparison village and the closest treatment village in the sample was about 4.2 km. However, over the three years after the baseline survey was conducted, the Cambodia HARVEST program interventions were extended to other villages in the same area. That reduced the average distance between a comparison village and any Cambodia HARVEST treatment village to only 1.4 km. So although the comparison villages were not intervened by HARVEST as per the design, selecting other treatment villages closer to the comparison villages potentially increased the spillover effects of treatment and reduced the ability to detect program effects.

7.2. Project Setting

Cambodia HARVEST coverage was limited to selected districts and villages in four target provinces (FTF zone of influence). This formed the definition of the study area for this evaluation. However, according to the survey, farmers in comparison villages within the study area reported receiving interventions from other NGO-funded projects and by the government. These other development interventions were promoting similar technologies or innovations—i.e., new rice varieties, home gardens, and nutrition education. The lack of discernible impacts could be due to the presence of these other interventions in comparison villages, which may have diluted the net program effects that can be attributed to Cambodia HARVEST.

7.3. Project Implementation Approach

It is also worth noting the way that Cambodia HARVEST was implemented to provide a context to the results. First, the service delivery approach of Cambodia HARVEST included providing intensive technical assistance to clients for a period of 18 to 24 months, then graduating them and moving on to other villages and clients. Over the five years, the project’s implementation strategy had evolved (as it should) on the basis of internal reflections and an external midterm review. However, the sample of farmers selected for this evaluation predominantly represented the first cohorts of Cambodia HARVEST beneficiaries. This means that the results of this evaluation may not reflect some of the evolution and improvements in the Cambodia HARVEST project implementation that may have taken place in the later years.

The service delivery approach that included intensive technical assistance to clients also had its own limitations that could have contributed to the lack of program effect on key indicators. Cambodia HARVEST as a project hired its own extension workers and did not utilize or collaborate with extension officers of the Royal Government of Cambodia. As a result, clients had no contact with extension service providers after their participation in Cambodia HARVEST ended. The project moved to other districts/villages after one or two crop cycles, so there was no reinforcement for sustainable adoption of new technology.
As indicated by the survey results, there was a huge increase (after 2011) in the awareness and uptake of some of the technologies promoted by the project, and this can be attributed to the Cambodia HARVEST (and other) program interventions in the study area. However, from 2012 to 2016, there was also a large gap between awareness and first-time uptake, and between uptake and current adoption. It seems that only 50% of farmers who become aware of a new technology made a decision to try it, and only 50% of those that tried it continued to use the technology a few years later. Of those who were aware of a new practice but did not adopt it, the main reasons given were non-availability of inputs, labor constraints, high cost, and lack of technical assistance. At least two of these constraints—availability of inputs and technical assistance—and potentially a third one (cost) are issues that Cambodia HARVEST could have addressed if it had had an exit strategy that didn’t leave a void once a village was graduated. But anecdotal evidence indicates that many did not start a business or discontinued their business and migrated to cities or neighboring countries for employment. More qualitative studies focused on the sustainability of these businesses or input suppliers and farmer surveys focused on technology adoption behavior after graduating from Cambodia HARVEST as a client would have been important to shed some light on the reasons for low rates of adoption of these technologies promoted by the project.

7.4. Time Lags in Influencing Impact Indicators along the Pathway

The focus of this impact evaluation was to assess whether and by how much the project activities contributed to higher income, expenditures, better quality of food consumption (as measured by dietary diversity), adoption of good infant and young child feeding practices, and improvements in nutritional outcomes as reflected in stunting, wasting, and underweight in children under 5 years of age, and underweight among women of childbearing age. The main pathways by which the project was expected to influence these outcomes were production (i.e., technology adoption), consumption (nutrition education and programs), and policy changes. The lack of discernible effects of these efforts on the impact indicators examined along the pathways could be due to the low magnitude of effects, which were not adequate to trigger cascading effects down the pathways and generate sustainable changes in farm practices, food preparation practices, food consumption behavior, and hygiene habits. It is also possible that this evaluation may have taken place in a time frame (recall that on average the treated household had most participated in 2013-2014, two years before the endline survey) when these impacts were still not realized. Realization of impacts on some of the downstream indicators needs consistent efforts from change agents and institutional arrangements for getting agriculture moving.

In conclusion, the reasons identified above—i.e., sample size, non-conformity of treatment households, contamination of control group due to spillover effects, evolving nature of a program, time lags, etc.—are common issues that pose practical challenges in conducting rigorous impact evaluations that require pre- and post-treatment data from both treatment and comparison groups. Large-scale and comprehensive development projects such as Cambodia HARVEST rarely have all the five years of their program mapped out in year 1, when the treatment and comparison groups need to be identified, and baseline data need to be collected. Such projects are often designed to tackle complex development challenges using multipronged approaches, which makes it difficult to define the treatment that should be the focus of such evaluation. The strategy and geographic scale of such projects also evolve and expand over time. These complexities make it difficult to come up with an adequate sample
of treatment group and comparison group that would be representative of the project’s changing strategy and focus over time.

Rigorous impact evaluation can yield strong evidence of the causal effects of a program. But this is not practical in all settings. The issues and challenges identified in this study should provide some guidance on the appropriateness of rigorous impact evaluations of such large-scale, comprehensive development projects. In a setting where it will be difficult to maintain a comparison group free of contamination (as was the case in this study setting), rigorous impact evaluations based on treatment and control group comparisons at a program level should be avoided. Perhaps employing rigorous impact evaluations focused on answering specific questions about the effectiveness of alternate approaches (especially, if they have cost implications for scaling up) for achieving a targeted result would be more appropriate than designing such rigorous large-scale impact evaluations to examine the effects of a complex program as a whole. One example of a rigorous impact evaluation focused on a specific question in the context of this study is testing the effectiveness of minimum type (i.e., length, intensity) of support required to ensure continued use of improved technologies by farmers after they graduate as program clients.

This study also points to the importance of identification and early involvement of impact evaluators in all aspects of the evaluation design and decision making on critical aspects that can affect the integrity of the design. This includes involvement by evaluators in sample selection (especially of the comparison group), periodic updates from project implementers on any changes in the project design or approach, and opportunity for evaluation partners to participate in discussions with the project implementation team to ensure future expansion of project activities does not compromise the buffer zone needed around the selected comparison group to minimize contamination.

ANNEX 1. SUMMARY OF CAMBODIA HARVEST ACHIEVEMENTS

Source: Cambodia HARVEST: Final Report (Fintrac 2016a).
ANNEX 2. SAMPLING METHOD AND APPROACH USED TO COLLECT BASELINE DATA IN 2012

A2.1. Population and Sampling Frame

Cambodia HARVEST program targeted to work with 70,000 households i.e., 22,610 households receiving direct technical assistance and 47,390 households receiving indirect assistance in the same areas. Of these populations, 15,000 households located within 150 villages of the four target provinces of Pursat, Battambang, Siem Reap and Kampong Thom were targeted to receive agriculture extension services training (on home gardens, commercial horticulture, fish ponds, rice), nutrition training, and credit and marketing assistance. The remaining 7,610 households were targeted to receive direct assistance from other HARVEST interventions such as forestry, fishery, mobile kitchen, vocational training, fish processing, Small and Medium Enterprises (SMEs) and agro-businesses.

Given the last projected program coverage, the Cambodia HARVEST impact evaluation design used a multi-stage cluster sampling approach, with households as the basic sampling unit. The sample size was designed to provide robust, accurate and precise results that minimize the burden of sampling error rate and statistically represent the study samples. In the most conservative approach, sample size of 2,100 was estimated based on a 95% confidence level (5% error) with a power of 80%, which means there is at least 80% chance of detecting changes/effects in the study samples with a 95% confidence level.

Based on feasibility and desirability, the total sample of 2,100 households was split 70:30 between treatment and comparison villages. Thus, 60 village clusters were selected for the treatment group and 24 (six per province) for the comparison group. The distribution of the sample size by provinces and by project phases (1 and 2) is outlined in Table A2.1.

A2.2. Village Sample Selection

The first step of the two-stage cluster sampling procedure was to select villages for the Cambodia HARVEST treatment and comparison group, and the second step was to randomly select households from each village cluster for the baseline and end of project impact evaluation surveys.

Table A2.1. Sampling Framework for Cambodia HARVEST Impact Evaluation Baseline Survey.

A2.2.1. Selection of Treatment Clusters/Villages: At the time of designing the baseline survey, Cambodia HARVEST had already started interventions in 105 villages (Phase I villages) and had plans to expand their activities to another 45 villages in 2013 (Phase II villages). On average, a village comprised of 233 households and Cambodia HARVEST anticipated working directly with 50 to 100 households per village. The list of Phase I and Phase II villages with client households was obtained from the Cambodia HARVEST office. This data was used to construct the sampling frame for selecting villages or clusters for treatment group.

The impact evaluation guideline designed by MSU suggested that 50% of treatment group villages should be selected from Phase I list and 50% from phase II list. In practice, however, CDRI was not able to follow this guideline, because Fintrac did not have sample villages to select Phase II villages. At the time of survey there were only 12 villages identified for Phase II that had enough Cambodia HARVEST clients for the sampling exercise, and thus all of them were selected.

For selecting Phase I village group, Fintrac provided a list of 105 villages, but some villages did not have enough Cambodia HARVEST clients for sample selection (for baseline data collection purposes, HARVEST clients that had received assistance before December 2011 were considered unqualified for sample selection). Therefore, villages that did not have enough clients were dropped and 48 villages were randomly selected from the list of remaining phase I villages. By adjusting Phase I and Phase II villages across provinces, the final sample of clusters or villages was reached in the desired proportion 25:25:25:25 percent for Pursat, Battambang, Siem Reap and Kampong Thom provinces, respectively (Tables A2.1).

A2.2.2. Comparison Clusters/Villages: The criteria for selecting comparison villages was that they had to be located near the Cambodia HARVEST project areas and were not being considered by Cambodia HARVEST expansion in the future. The comparison villages sought had similar socioeconomic characteristics, crops and fisheries, road infrastructure, and soil and climatic conditions, and were distant enough to have no spillover effects from the Cambodia HARVEST treatment villages. Fintrac provided a list of 40 villages (10 per province), which were located near the intervention villages (to ensure they were similar in characteristics as the treatment villages). Six villages per province were randomly selected from this list, giving a total of 24 comparison clusters (Tables A2.1).

A2.3. Selection of Household Samples

A2.3.1. Treatment Household Sample: The impact evaluation design prepared by MSU suggested that treatment groups be composed of rice, home garden, and fishpond client households. The client list provided by Fintrac was used to first filter out all the households that had already received technical assistance that could have impacted the 2011-12 agricultural production cycle. The list comprised mostly of home garden clients followed by rice and fishpond clients. Therefore, client households were selected using the ratio 40:30:30 percent, that is 10 home garden clients: 8 rice clients: 7 fishpond clients. In the Phase I villages, some households had received two of these three technical services, and some had received all three. Even if a household was targeted to receive two or three technical services, it was classified as one client in the sample selection. In each cluster village fishpond client households were selected first, followed by rice client households. If fishpond and/or rice clients made up less than 30% of the total clients in a village, they were all selected. In most
cases, fishpond and rice clients comprised more than 30% of total clients (25 HHs per village) per village, and home garden clients more than 50% of total clients. Therefore, the remaining household clients in each village were adjusted by adding home garden client households using systematic random sampling, though some villages had only home garden clients.

A2.3.2. **Comparison Household Sample:** It was not feasible to use the 2008 Census as the sample frame to select households for the comparison group because of population movements due to migration. Instead, enumerator team leaders with the help of village leaders made a list of households in each village. These village household lists were used as the sampling frame and systematic random sampling was applied to select households for the comparison group.

A2.3.3. **Method of Household Selection:** For villages where a list of household was available to select the desired number of households, the following method was used. First, a random number was obtained by using the last digit of the serial number on the first bank note pulled from a pocket. That number was then used to select the first household on the list and then every household at the same interval to reach the desired number of sample households for each cluster village. In all villages, both treatment and comparison, two to three households were selected as reserve households in case selected households could not be found during the field survey.
