Technical and Water Use Efficiency in Methods of Irrigation in Thane District of Maharashtra*

J.M. Talathi¹ and G.K. Hiremath²

Abstract

The paper has examined the nature of technological change in the irrigated crop production in the Thane district of Maharashtra by taking the cross-sectional data from 173 farms. The Cobb-Douglas production function analysis on per hectare basis has indicated that human labour (0.0613) has a significant and positive influence on output in traditional method of irrigation (TMI). In the modern method of irrigation (MMI), fertilizer (0.4612) followed by human labour (0.3180) have significant but negative influence on crop productivity. In TMI farms the quantity of water used has been excess by 27 per cent over the economic optimum while in MMI farms, it has been only marginally higher (0.38%) over economic optimum. It reveals water conservation in MMI. The average Timmer technical efficiencies have been found as 49.97 per cent in TMI and 58.37 per cent in MMI for the irrigated crop production. There has been excessive use of factors of production (human labour, bullock labour, seed, manure, fertilizer, plant protection and irrigation expenses) to the extent of 78 to 92 per cent in TMI and 30 to 37 per cent in MMI, as revealed through frontier production function analysis for frontier users. It indicates the existence of much scope in efficient use of inputs in TMI.

Introduction

Water, as an input to agriculture, is vital to economic growth and sustainable development. Its catalytic role in enhancing productivity and improving resource-use efficiency is well documented. However, water

* Based on the Ph.D. Thesis submitted to the University of Agricultural Sciences, Dharwad – 580 005
has become a scarce resource, owing to its multiple uses and increasing demand in crop production. The question is how to make judicious use of water. Although there are a number of price and non-price factors that have a role in improving water-use efficiency, the irrigation technology plays an important role in it. There are different methods of irrigation — each having its own advantages and limitations. This paper has examined the nature of technological change in the irrigated crop production in the Thane district of Maharashtra where drip irrigation method is practised, particularly by the farmers growing fruits and vegetables. Being in proximity to Mumbai, there is an assured market for fruits and vegetables. The rising water scarcity has forced the farmers to switch over to improved irrigation methods as to reduce the cost of production and increase crop yields.

Methodology

Sample

The sample respondents were selected using the multi-stage random sampling technique. The primary data required for the study were collected through a survey of 173 farmers from 9 villages spread across three talukas of the Thane district during the agricultural year 1997-98. The sample farms were further divided into two categories as those practising (i) traditional method of irrigation (TMI), i.e. flood/check basin irrigation, and (ii) modern method of irrigation (MMI), i.e. drip irrigation using groundwater. The distribution of sample is given in Table 1.

Analytical Tools

Production Function

Separate production functions (log linear) were estimated for measuring the change in farm productivity between the traditional and modern methods of irrigation. The functions were:

For traditional method [Eq. (1)]:

\[ \ln Y_1 = \ln a_1 + b_{11} \ln X_{11} + b_{12} \ln X_{12} + \ldots + b_{1n} \ln X_{1n} + e_1 \]

Marginal Productivity of Groundwater

The marginal productivity of groundwater was estimated using a gross return function of the transcendental form since it allowed for variability in marginal productivity and elasticity of water-use. It was hypothesized that the gross income would vary with groundwater used and irrigation costs. In addition, the marginal productivity of water was hypothesized to vary inversely with the level of water used and directly with the gross returns. Transcendental function by virtue of its property to accommodate the increasing, decreasing and diminishing returns to water used. The functional form was given by Equation (3):

\[
Y = A X_1^{B_1} e^{C_1 X_1} X_2^{B_2} e^{C_2 X_2}
\]  

where,

- \(Y\) = Gross returns from the farm (Rs)
- \(X_1\) = Groundwater use (lakh litres)
- \(X_2\) = Annual cost of irrigation (Rs)

Equation (3) was estimated with the following form [Eq. (4)]:

\[
\ln Y = \ln A + B_1 \ln X_1 + C_1 X_1 + B_2 \ln X_2 + C_2 X_2
\]  

The marginal productivity of groundwater was estimated by using the expression (5):

\[MP_{GW} = \frac{B_1}{X_1 + C_1} Y\]
and was estimated at the geometric mean level of gross return and groundwater used.

The optimum dose of groundwater was estimated by using expression (6):

\[ X_i^* = \frac{(B_1 Y)}{(P_{x1} - C_i Y)} \]  

...(6)

where, \( P_{x1} = \) Price per unit of water = (Amortized cost of irrigation for the entire farm/quantity of water used in the farm (lakh litres).

The Timmer Measure of Technical Efficiency

Timmer imposed a Cobb-Douglas type specification on the frontier and computed an output-based measure of efficiency. The approach adopted was to specify a fixed parameter frontier amenable to the statistical analysis. The general form of production function was given as Equation (7):

\[ Y = f(X) e^u \]  

...(7)

\( U \leq 0 \)

and Cobb-Douglas production function in natural logarithmic form [Eq. (8)]:

\[ \ln Y = \sum_{i=1}^{n} b_i \ln X_i + U_i \]  

...(8)

where, \( U_1 \leq 0 \)

In estimating the frontier production function, Corrected Ordinary Least Squares (COLS) was chosen as the most convenient means. As a first step, OLS was applied to the C-D production function to obtain the best unbiased estimates of bi-coefficients. The constant (intercept) estimate was then corrected by shifting the function until no residual was positive and one function was zero. It was done by adding the largest error-term of the fitted model to the intercept.

The Timmer measure of technical efficiency of a farm is the ratio of the actual output to the potential output given the level of input-use on farm ‘i’. It thus indicates how much extra output could be obtained if farm ‘i’ were to be on the frontier.

Timmer measure of technical efficiency is given by Equation (9):

\[ TE = \frac{Y}{Y^*} \]  

...(9)
where,

\( Y^* = \) The maximum obtainable output given the levels of the inputs (frontier output).

**The Kopp Measure of Technical Efficiency**

Kopp (1981) suggested a different measure of technical efficiency in which the actual level of input used is compared to the level which would be used if farm ‘i’ were to be located on the frontier, given the actual output of farm ‘i’ and given the same ratios of input usage.

If

\[ \ln Y = a + b_1 \ln X_1 + b_2 \ln X_2 + \ldots + e \]

Let

\[ R_1 = \frac{X_1}{X_2}, \quad R_2 = \frac{X_3}{X_2}, \ldots, R_n = \frac{X_n}{X_2} \]

where, \( X_1, X_2, \ldots, X_n \) denote the optimum use of inputs.

Then

\[ \ln X_2 = \ln X_3, \ldots \] and \( \ln X_n \) can be calculated in a similar fashion.

\[ \ln X_2^* = (\ln Y - A^* - b_1 \ln x_1 - b_2 \ln x_2 - \ldots - b_n \ln x_n) / \sum b_i \]

Then we may compute

\[ \text{TE}_i = \frac{X_2^*}{X_2} = \frac{X_1^*}{X_1} = \frac{X_3^*}{X_3} = \ldots = \frac{X_n^*}{X_n} \]

Using Kopp measure of technical efficiency, the frontier usage of input was worked out and compared with the actual usage of inputs.

**Results and Discussion**

**Resource-use Efficiency**

Coefficients of human labour (0.8645) and irrigation expenses (0.0613) (Table 2) were positive and significant on farms using traditional method of irrigation. These farms had higher proportion of vegetables in their cropping pattern than the MMI farms. However, the availability of labour, especially during the peak periods, was inadequate as perceived by the farmers. This implied that human labour was an important factor in irrigated crop production. The negative regression coefficient of bullock labour showed its excess use in the irrigated crop production due to non-availability of alternative avenues for engaging the bullocks.

*Significant at 10% level

Note: Figures within the parentheses indicate standard error of respective production coefficient

Fertilizers (0.4612) followed by human labour (0.3180) (Table 2) had significant and positive influence while plant protection (-0.1072) had significant but negative influence under MMI. The farms with MMI used higher quantities of fertilizers to obtain better yields of vegetables and fruits. The negative influence of plant protection chemicals in MMI also indicated their excess use. The production elasticities of other variables were positive but their influence on productivity was not significant.

Further, the variables included in the functions exhibited constant returns to scale in the traditional method of irrigation and increasing returns to scale in the modern method of irrigation.

Water-use Efficiency and Marginal Productivity

In a well command area, the actual groundwater used was 28.50 lakh litres in MMI and 20.70 lakh litres in TMI. However, the economic optimum using transcendental production function was estimated at 28.39 lakh litres in MMI and 16.28 lakh litres in TMI. The MR (marginal revenue) to MC (marginal cost) ratio was 1.00 in MMI and 0.92 in TMI.

In the case of MMI, MR to MC ratio (1.00) had reached the economic optimum of groundwater-use. These farms were using marginally excess water over economic optimum. On the other hand, in the case of TMI, water-use was 27 per cent excess over the economic optimum.

The MMI farms had more area under irrigation than the traditional farms, may be due to their higher water-use efficiency and adopted conservation measures. In both the groups of farms, almost all the farmers grew those vegetable crops which used less water. Satyasai and Vishwanathan (1997) have made similar observations in Andhra Pradesh on different crops.

Timmer Measure of Technical Efficiency

The results of Timmer measure of technical efficiency are given in Table 3. The mean technical efficiency of 58.37 per cent on MMI farms was higher than that on TMI farms (49.97%). Only 13.85 per cent of the TMI farms had technical efficiency above 75 per cent, while none of the MMI farms had such a high technical efficiency. In most of the MMI farms, the technical efficiency ranged between 50 and 75 per cent. The proportion of TMI farms within this range was only 46 per cent, while rest of the TMI farms had technical efficiency below 50 per cent. These observations

</table>
indicated that there was scope in improving the technical efficiency levels on both the TMI and MMI farms through suitable modifications in input-use.

Kopp Measure of Technical Efficiency

The actual and frontier levels of factors of production for both the TMI and MMI are presented in Table 4. In general, the inputs were used excessively under TMI than MMI farms. The quantum of excessive use ranged from 78.38 to 92.32 per cent on TMI and 30.44 to 38.91 per cent on MMI farms. In other words, farmers practising TMI had a greater scope to increase their output with the existing level of inputs than the MMI practitioners. The efficiency results, by and large, were in conformity with those of Russel and Young (1983), Ali and Chowdhary (1991) and Kalirajan and Shand (1997). Alternatively, it suggested that modern methods of irrigation add to input-use efficiency.

Conclusions

The estimated farm level production response functions have been significant and a good fit has been found for both traditional and modern methods of irrigation. The Cobbs-Dugas function analysis has indicated that the human labour (0.8645) and irrigation expenses (0.0613) have a significant and positive influence while bullock labour (-0.0212) has a significant but negative influence on output on TMI farms. In case of MMI farms, fertilizer (0.4612) followed by human labour (0.3180) have a significant and positive influence while plant protection (-0.1172) has a significant but negative influence on crop productivity. The coefficient of multiple determination ($R^2$) (0.91 in TMI and 0.94 in MMI) was on fairly higher side.

The traditional methods of irrigation result in excess water-use, while the modern methods promote optimum utilization of water, implying that modern methods of irrigation conserve water that can be used to irrigate additional land area. The magnitude of input-use has been higher in the traditional than modern methods. This suggests a greater scope for the efficient use of inputs in the traditional method of irrigation.
