THE COMPARISON OF TWO OR MORE STATIONARY TIME SERIES

Ann Maharaja

Working Paper 12/97
= November 1997

# THE COMPARISON OF TWO OR MORE STATIONARY TIME SERIES 

Ann Maharaj<br>Department of Econometrics and Business Statistics<br>Monash University<br>Melbourne, Australia

#### Abstract

In this paper we propose a test statistic to compare two or more stationary time series that are not necessarily independent. The test is based on the difference between estimated parameters of the autoregressive models that are fitted to the series.

## 1. INTRODUCTION

The comparison of time series has applications in various fields including economics, geology, engineering and climatology. Hypothesis tests designed to compare two stationary independent time series involving the use of fitted parameter estimates were considered by De Souza and Thomson (1982) and Maharaj (1996). Other tests in the literature for the comparison of two independent stationary series involve the use of the estimated spectra of the series. Some relevant papers are by Jenkins (1961), Swanepoel and Van Wyk (1986), Coates and Diggle (1986) and Diggle and Fisher (1991). In practice the application of these tests to real time series is limited since comparisons are often made between logically connected series and in some instances, one may wish to make comparisons between more than two series.

We will consider the comparison of two or more stationary time series that are not necessarily independent. We will assume that if the series are not stationary, then the same order of differencing will be needed to make each one stationary. Truncated $\operatorname{AR}(\infty)$ models of order $k$, are fitted to each series. and the test statistic is based on the difference between the $\operatorname{AR}(\mathrm{k})$ estimates. These estimates are generalised least squares estimates. It will be assumed that the disturbances of the models are correlated for series that are not independent and uncorrelated for series that are independent. In Section 2 we present the test statistic and in Section 3 a simulation study is carried out to investigate the distributional properties, size and power of this test statistic, which has an asymptotic chi-square distribution. In Section 4 we make power comparisons with some of the existing tests for independent series in the literature and in Section 5 we apply the test based on this test statistic to a set of economic time series and to a set of time series in climatology.

## 2. HYPOTHESIS TESTING PROCEDURE

Let $\mathrm{Z}_{\mathrm{t}}$ be a zero mean univariate stochastic process such that $\mathrm{Z}_{\mathrm{t}} \in L$ where $L$, is the class of stationary and invertible ARMA models. Using the standard notation of Box and Jenkins (1976), such a model is defined as

$$
\phi(B) Z_{t}=\theta(B) a_{t}
$$

where $\mathrm{a}_{\mathrm{t}}$ is a univariate white noise process with mean 0 and variance, $\sigma_{a}{ }^{2}$ and where

$$
\begin{aligned}
& \phi(B)=1-\phi_{1} B-\phi_{2} B^{2}-\ldots-\phi_{p} B^{p} \\
& \theta(B)=1-\theta_{1} B-\theta_{2} B^{2}-\ldots-\theta_{q} B^{q}
\end{aligned}
$$

with the usual stationarity and invertibility restrictions on the roots of $\phi(B)$ and $\theta(B)$.

$$
Z_{t}=\sum_{j=1}^{\infty} \pi_{j} Z_{t-j}+a_{t}
$$

where

$$
\Pi(B)=\phi(B) \theta^{-1}(B)=1-\pi_{1} B-\pi_{2} B^{2}-\ldots
$$

Let $\left\{\mathrm{x}_{\mathrm{t}}\right\}, \mathrm{t}=1,2, \ldots, \mathrm{~T}, \mathrm{i}=1,2, \ldots, \mathrm{q}$, be q stationary correlated series. Then using a definite criterion such as Schwartz's BIC for modelling AR structures, truncated $\operatorname{AR}(\infty)$ models of order $\mathrm{k}_{\mathrm{i}}$, can be fitted to each corresponding $\left\{\mathrm{x}_{\mathrm{t}}\right\}, \mathrm{i}=1,2, \ldots, \mathrm{q}$. Define the vector of the $\operatorname{AR}\left(\mathrm{k}_{\mathrm{i}}\right)$ parameters of the i th generating processes $\mathrm{X}_{\mathrm{ti}}$ as

$$
\Pi_{i}^{\prime}=\left[\begin{array}{llll}
\pi_{1 i} & \pi_{2 i} & \ldots & \pi_{k_{i} i}
\end{array}\right], \quad \mathrm{i}=1,2, \ldots, \mathrm{q}
$$

and the corresponding $\operatorname{AR}\left(\mathrm{k}_{\mathrm{i}}\right)$ parameter estimates of the series $\left\{\mathrm{x}_{\mathrm{t}}\right\}$ as

$$
\hat{\pi}_{\mathrm{ji}}, \quad \mathrm{j}=1,2, \ldots, \mathrm{k}_{\mathrm{i},}, \quad \mathrm{i}=1,2, \ldots, \mathrm{q} .
$$

Let $k=\max \left(k_{1}, k_{2}, \ldots, k_{q}\right)$. In constructing the test statistic the maximum order $k$ is assumed to be fitted to all series. Then define

$$
\hat{\Pi}_{\mathrm{ki}}^{\prime}=\left[\hat{\pi}_{\mathrm{li}}, \hat{\pi}_{2 \mathrm{i}}, \ldots, \hat{\pi}_{\mathrm{ki}}\right], \mathrm{i}=1,2, \ldots, \mathrm{q} .
$$

The hypotheses to be tested are:
$\mathrm{H}_{0}$ : There is no significant difference between the generating processes of q stationary series (i.e. $\Pi_{\mathrm{k} 1}=\Pi_{\mathrm{k} 2}=\ldots=\Pi_{\mathrm{kq}}=\Pi_{\mathrm{k}}$ ).
$\mathrm{H}_{1}$ : There is a significant difference between the generating processes of at least two stationary series.

The model to be fitted is of the form of 'the seemingly unrelated regressions model' as proposed by Zellner (1962). The T-k observations of the models fitted to the $q$ series $\left\{x_{i t}\right\}, i=1,2, \ldots, q$, can be expressed collectively as

$$
\begin{equation*}
\mathrm{x}_{\mathrm{i}}=\mathrm{W}_{\mathrm{i}} \Pi_{\mathrm{ki}}+\mathrm{a}_{\mathrm{i}} \tag{2.1}
\end{equation*}
$$

where

$$
\mathrm{x}_{\mathrm{i}}^{\prime}=\left[\begin{array}{llll}
\mathrm{x}_{\mathrm{k}+1 \mathrm{i}} & \ldots & \mathrm{x}_{\mathrm{T}-1 \mathrm{i}} & \mathrm{x}_{\mathrm{Ti}}
\end{array}\right]
$$

$$
\begin{aligned}
& \Pi_{\mathrm{ki}}^{\prime}=\left[\begin{array}{lllll}
\pi_{\mathrm{li}} & \pi_{2 \mathrm{i}} & \cdot & \cdot & \cdot \\
\pi_{\mathrm{ki}}
\end{array}\right] \\
& \mathrm{a}_{\mathrm{i}}^{\prime}=\left[\begin{array}{lllll}
\mathrm{a}_{\mathrm{k}+1 \mathrm{i}} & \cdot & \cdot & a_{\mathrm{T}-1 \mathrm{i}} & a_{\mathrm{Ti}}
\end{array}\right]
\end{aligned}
$$

and

$$
\mathrm{E}\left[\mathrm{a}_{\mathrm{i}}\right]=0 \quad \mathrm{E}\left[\mathrm{a}_{\mathrm{i}} \mathrm{a}_{\mathrm{i}}^{\prime}\right]=\sigma_{\mathrm{i}}^{2} \mathrm{I}_{\mathrm{T}-\mathrm{k}}
$$

and where $\mathrm{I}_{\mathrm{T}-\mathrm{k}}$ is a (T-k) $\mathrm{x}(\mathrm{T}-\mathrm{k})$ identity matrix. We will assume that the disturbances of the q models are correlated at the same points in time but uncorrelated across observations. That is

$$
E\left(a_{i} a_{j}^{\prime}\right)=\sigma_{i j} I_{T-k} \quad i, j=1,2, \ldots, q
$$

Then assuming that a total of (T-k)q observations are used in estimating the parameters of the $q$ equations in (2.1), the combined model may be expressed as

$$
\begin{equation*}
Z=W \Pi+a \tag{2.2}
\end{equation*}
$$

where

$$
\begin{array}{lc}
Z=\left[\begin{array}{c}
x_{1} \\
x_{2} \\
\cdot \\
\cdot \\
\cdot \\
x_{q}
\end{array}\right] & \mathrm{W}=\left[\begin{array}{cccccc}
\mathrm{W}_{1} & 0 & \cdot & \cdot & 0 \\
0 & \mathrm{~W}_{2} & \cdot & \cdot & \cdot & 0 \\
\cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & \cdot & \cdot \\
0 & 0 & \cdot & \cdot & W_{q}
\end{array}\right] \\
\Pi=\left[\begin{array}{c}
\Pi_{\mathrm{k} 1} \\
\Pi_{\mathrm{k} 2} \\
\cdot \\
\cdot \\
\cdot \\
\Pi_{\mathrm{kq}}
\end{array}\right] & \mathrm{a}=\left[\begin{array}{c}
\mathrm{a}_{1} \\
\mathrm{a}_{2} \\
\cdot \\
\cdot \\
\cdot \\
a_{\mathrm{q}}
\end{array}\right]
\end{array}
$$

and

$$
\begin{aligned}
& \mathrm{E}(\mathrm{a})=0 \\
& \mathrm{E}\left(\mathrm{aa}^{\prime}\right)=\mathrm{V}=\Sigma \otimes \mathrm{I}_{\mathrm{T}-\mathrm{k}}
\end{aligned}
$$

where

$$
\Sigma=\left[\begin{array}{ccccc}
\sigma_{1}^{2} & \sigma_{12} & \cdot & \cdot & \sigma_{1 q} \\
\sigma_{12} & \sigma_{2}^{2} & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & \cdot \\
\sigma_{1 q} & \sigma_{2 q} & \cdot & \cdot & \cdot \\
\sigma_{\mathrm{q}}^{2}
\end{array}\right] .
$$

The generalised least squares estimator is

$$
\begin{equation*}
\hat{\Pi}=\left[W^{\prime} V^{-1} W\right]^{-1} W^{\prime} V^{-1} Z \tag{2.3}
\end{equation*}
$$

Assuming that disturbances are normally distributed, then by results in Anderson (1971) amongst other authors, $\hat{\Pi}$ has been shown to be asymptotically normally distributed with mean $\Pi$ and covariance matrix

$$
\lim _{\mathrm{T} \rightarrow \infty} \operatorname{Var}(\sqrt{\mathrm{~T}} \hat{\Pi})=\operatorname{plim}\left(\frac{\mathrm{W}^{\prime} \mathrm{V}^{-1} \mathrm{~W}}{\mathrm{~T}}\right)^{-1} .
$$

Now

$$
\mathrm{H}_{0}: \Pi_{\mathrm{kx} 1}=\Pi_{\mathrm{kx} 2}=\ldots=\Pi_{\mathrm{kxq}}
$$

may be expressed as

$$
\mathrm{H}_{0}: \mathrm{R} \Pi=0
$$

where $R$ is a $k(q-1) x$ kq matrix where each row consists of a one, ( $k q-2$ ) zeros and a minus one, namely

$$
\mathrm{R}=\left[\begin{array}{cccccccc}
1 & 0 & -1 & 0 & . & . & . & 0 \\
0 & 1 & 0 & -1 & 0 & . & . & 0 \\
. & . & . & . & . & . & . & . \\
. & . & . & . & . & . & . & . \\
. & . & . & . & . & . & . & . \\
0 & 0 & . & . & 1 & 0 & 0 & -1
\end{array}\right] .
$$

Hence $R \hat{\Pi}$ is asymptotically normally distributed with mean $R \Pi$ and covariance matrix

$$
\lim _{\mathrm{T} \rightarrow \infty} \operatorname{Var}(\sqrt{\mathrm{~T} R \hat{\Pi})})=\operatorname{plim} \frac{\mathrm{R}\left(\mathrm{~W}^{\prime} \mathrm{V}^{-1} \mathrm{~W}\right)^{-1} \mathrm{R}^{\prime}}{\mathrm{T}} .
$$

Let

$$
\begin{equation*}
\mathrm{F}=\left(\mathrm{R}\left(\mathrm{~W}^{\prime} \mathrm{V}^{-1} \mathrm{~W}\right)^{-1} \mathrm{R}^{\prime}\right)^{-1 / 2}(\mathrm{R} \hat{\Pi}-\mathrm{R} \Pi) \tag{2.4}
\end{equation*}
$$

Then by substituting (2.3) into (2.4), F becomes

$$
F=\left[R\left(W^{\prime} V^{-1} W\right)^{-1} R^{\prime}\right]^{-1 / 2} R\left(\left(W^{\prime} V^{-1} W\right)^{-1} W^{\prime} V^{-1}(W \Pi+a)-\Pi\right) .
$$

Under $\mathrm{H}_{0}$

$$
F=\left[R\left(W^{\prime} V^{-1} W\right)^{-1} R^{\prime}\right]^{-1 / 2} R\left(W^{\prime} V^{-1} W\right)^{-1} W^{\prime} V^{-1} a
$$

Under the assumption that

$$
\begin{aligned}
& \mathrm{a} \sim \mathrm{~N}(0, \mathrm{~V}) \\
& \mathrm{E}(\mathrm{~F})=0 \text { and } \mathrm{E}\left(\mathrm{FF}^{\prime}\right)=\mathrm{I}_{\mathrm{k}}, \\
& \mathrm{~F} \\
& \stackrel{A}{\sim} \mathrm{~N}\left(0, \mathrm{I}_{\mathrm{k}}\right) .
\end{aligned}
$$

Therefore

$$
F^{\prime} F=(R \hat{\Pi})^{\prime}\left[R\left(W^{\prime} V^{-1} W\right)^{-1} R^{\prime}\right]^{-1}(R \hat{\Pi}) \stackrel{A}{\sim} \chi^{2}(k(q-1))
$$

Since $\Sigma$ is unknown, a feasible generalised least squares estimator of $\Pi$ will have to be used. By Zellner (1962), least squares residuals may be used to estimate consistently the elements of $\Sigma$ with $\hat{\sigma}_{i}^{2}=\frac{\hat{a}_{i}^{\prime} \hat{a}_{i}}{T-k}$, and $\hat{\sigma}_{i j}=\frac{\hat{a}_{i}^{\prime} \hat{a}_{j}}{T-k}$.

Hence the feasible generalised least squares estimator is

$$
\begin{equation*}
\hat{\Pi}=\left[W^{\prime} \hat{V}^{-1} W\right]^{-1} W^{\prime} \hat{V}^{-1} Z \tag{2.5}
\end{equation*}
$$

with

$$
\lim _{\mathrm{T} \rightarrow \infty} \operatorname{Var}(\sqrt{\mathrm{~T}} \hat{\mathrm{\Pi}})=\operatorname{plim}\left(\frac{\mathrm{W}^{\prime} \hat{\mathrm{V}}^{-1} \mathrm{~W}}{\mathrm{~T}}\right)^{-1}
$$

where

$$
\hat{\mathrm{V}}=\hat{\Sigma} \otimes \mathrm{I}_{\mathrm{T}-\mathrm{k}} \quad \text { and } \quad \hat{\Sigma}=\left[\begin{array}{cccccc}
\hat{\sigma}_{1}^{2} & \hat{\sigma}_{12} & . & . & . & \hat{\sigma}_{1 \mathrm{q}} \\
\hat{\sigma}_{12} & \hat{\sigma}_{2}^{2} & . & . & . & \hat{\sigma}_{2 \mathrm{q}} \\
\cdot & \cdot & . & . & \cdot \\
\cdot & . & . & . & \cdot \\
\cdot & . & . & . & . & \cdot \\
\hat{\sigma}_{1 q} & \hat{\sigma}_{2 \mathrm{q}} & . & . & . & \hat{\sigma}_{\mathrm{q}}^{2}
\end{array}\right] .
$$

Since $\hat{\mathrm{V}}$ is nonsingular and $\operatorname{plim} \hat{\mathrm{V}}=\mathrm{V}$, it is easily seen that then under $\mathrm{H}_{0}$

$$
\begin{equation*}
\mathrm{D}=\mathrm{F}^{\prime} \mathrm{F}=(\mathrm{R} \hat{\Pi})^{\prime}\left[\mathrm{R}\left(\mathrm{~W}^{\prime} \hat{\mathrm{V}}^{-1} \mathrm{~W}\right)^{-1} \mathrm{R}^{\prime}\right]^{-1}(\mathrm{R} \hat{\Pi}) \stackrel{\mathrm{A}}{\sim} \chi^{2}(\mathrm{k}(\mathrm{q}-1)) \tag{2.6}
\end{equation*}
$$

## 3 <br> SIMULATION STUDY

### 3.1 Assessment of the Test for $q=2$

To investigate the finite sample behaviour of the test statistic $D$, series of lengths 50 and 200 are simulated from a number of ARMA processes. For $\mathrm{q}=2$ distributional properties of the test based on D are checked by obtaining estimates of the mean, variance, skewness of the test statistic and size of the test procedure This is done by applying the test to pairs of series simulated from $\operatorname{AR}(1)$ processes for $\phi=0$, $0.1,0.5,0.9, \mathrm{MA}(1)$ processes for $\theta=0.1,0.5,0.9, \mathrm{AR}(2)$ processes for $\phi_{1}=0.6, \phi_{2}=$ 0.2, MA(2) processes for $\theta_{1}=0.8, \theta_{2}=-0.6$ and $\operatorname{ARMA}(1,1)$ processes for $\phi=0.8, \theta$ $=0.2$. It is assumed that the correlation between disturbances of each pair of processes from which the series were generated are in turn $0,0.5$ and 0.9 . Estimates of size are obtained for the $5 \%$ and $1 \%$ significance levels. Estimates of power for the $5 \%$ and $1 \%$ significance levels are obtained by applying the test to series generated from the following processes: $\operatorname{AR}(1) \phi=0$ versus $\operatorname{AR}(1), \phi>0, \operatorname{AR}(1) \phi=0$ versus $\operatorname{AR}(2) \phi_{1}$ $=0, \phi_{2}>0$ and $\operatorname{AR}(1) \phi=0.5$ versus $\operatorname{AR}(1) \phi \neq 0.5$. This is again done by assuming that the correlation between disturbances of each pair of processes from which the series were generated are in turn $0,0.5$ and 0.9.

The order (up to 10 ) of the truncated AR model to be fitted to each series is determined by Schwartz's BIC. However in estimating the model in (2.1), the
maximum order k is fitted to both the series in each pair. The test statistic D is then obtained. This is repeated 2000 times. As well as obtaining size and power estimates for the various degrees of freedom, overall estimates of power and size are also obtained.

For series of length 50 , size is considerably overestimated and estimates of the mean, variance and skewness of the test statistic do not correspond closely to the respective theoretical values. The overall size estimates are shown in Table A3.1. Since the implication here is that the test does not perform well for series of this length, no further analysis is carried out on series of length 50 .

For $\mathrm{T}=200$, the results for which there are at least 100 test statistics corresponding to a particular degree of freedom are shown in Tables A3.2 to A3.4. We observe that the size estimates for the series simulated from the AR models are fairly close to the predetermined significance levels when the correct order k is fitted but size is often overestimated for other values of $k$. For the MA and ARMA models, for some values of $k$, the size estimates are fairly close to the predetermined significance levels but in other cases size is overestimated. Hence this often causes the overall estimates of size to be slightly overestimated. These overall size estimates are shown in Table A3.5. It is clear from the size estimates that size improves (i.e. gets closer to the nominal $5 \%$ and $1 \%$ levels) as the correlation between disturbances of processes from which the series are generated gets larger. It can be seen from Tables A3.2 to A3.4 that for those values of $k$ for which reasonably good size estimates are obtained, the estimates of the means, variances and skewness of the test statistic are very often fairly close to the theoretical means, variances and skewness respectively.

Power estimates based on at least 100 test statistics corresponding to particular degrees of freedom and overall power estimates based on all 2000 test statistics are given in Tables A3.6.1 to A3.8.2. From these results it appears that the test has reasonably good power for the series length $T=200$. It can also been seen that the power of the test improves as the correlation between disturbances of processes from which the series are generated gets larger.

### 3.2 Assessment of the Test for $q=3$

The same simulation scenario which is considered in Section 3.1 for obtaining estimates of the mean, variance, skewness of the test statistic and size of the test procedure is again considered but this time for $q=3$ (i.e. testing for significant differences between the generating processes of 3 series) and only for $\mathrm{T}=200$. Estimates of mean, variance and skewness of the test statistic and the size of the test are shown in Tables A3.9.1 to A3.9.3 and estimates of overall size are shown in Table A3.10. Just as for the case $\mathrm{q}=2$ in Section 3.1, size estimates for the series simulated from the AR models are fairly close to the predetermined significance levels when the correct order is fitted but size is often overestimated for other values of $k$. For the MA and ARMA models, for some values of $k$, the size estimates are fairly close to the predetermined significance levels but in other cases size is overestimated. Hence again, this often causes the overall estimates of size to be slightly overestimated. Observation of the overall size estimates in Table A3.10 reveal that size generally improves (i.e. gets closer to the nominal $5 \%$ and $1 \%$ levels) as the correlation between disturbances of processes from which the series are generated gets larger. However it can be seen that the overall size estimates are slightly larger than for the case $q=2$. In those cases for which reasonably good size estimates are obtained, the estimates of the
means, variances and skewness of the test statistic are very often fairly close to the theoretical means, variances and measures of skewness respectively.

## 4 POWER COMPARISONS

In this section we compare the power of our test for the case of two independent series with tests proposed by Jenkins (1961), Diggle and Fisher (1991) and Swanpoel and Van Wyk (1986). There is no evidence in the literature that Jenkins test was previously simulated whereas Diggle and Fisher and Swanepoel and Van Wyk simulated their tests and obtained estimates of size and power. All of these tests compare two independent stationary time series by comparing their estimated spectra.

Jenkins test requires one to obtain windowed periodogram ordinates and then use the equivalent number of independent windowed periodogram ordinates to construct a test statistic which has an approximate standard normal distribution. In obtaining estimates of size and power for $\mathrm{T}=200$ we use a rectangular window with every tenth ordinate assumed to be independent. The choice of the number of equivalent number of independent ordinates follows from guides in Jenkins (1961) and Chatfield (1975). The results are shown in Table A4.1. Diggle and Fisher's test which we replicate for $\mathrm{T}=200$ uses normalised cumulative periodograms ordinates and a randomozation test based on the Kolgomorov-Smirnov type test statistic. The results are shown in Table A4.2. Swanpoel and Van Wyk use bootstrap methods and three test statistics, namely a Chi-square type (CS), Kolmogorov -Smirnov type (KS) and a Kullback-Leiber type (KL) test statistic. We replicate these tests for $\mathrm{T}=200$ and the results are shown in Table A4.3 from where it is clear that there is very little power difference between the three tests

The power curves for the various cases mentioned in Section 3, for our test (AR), Jenkins test (J), Diggle and Fisher's test (DF) and the Kullback-Leiber type test of Swanapoel and Van Wyk (SW), at the 5\% of significance are shown in Figures 4.1 -4.3.

Figure 4.1 Power Curves for White noise versus $\operatorname{AR}(1) \phi>0$ (5\% level of Significance)

Figure 4.2 Power Curves for White noise versus $\operatorname{AR}(2) \phi_{1}=0, \phi_{2}>0$ ( $5 \%$ level of Significance)

Figure 4.3 Power Curves for White noise versus $\operatorname{AR}(1) \phi=0.5, \phi \neq 0.5$ (5\% level of Significance)

In all the above cases, the overall size estimates of our are slightly overestimated. As explained in Section 3, this is due to the overestimation of size when orders of the autoregressive model other than the correct orders were fitted. It can be seen from Tables A3.6.1, A3.6.2, A3.7.1, A3.7.2, A3.8.1 and A3.8.2 that even though the specific (i.e. when the correct AR order is fitted) and overall size estimates differ slightly, there is very little difference in the specific and overall power estimates. So even though size estimates of the other tests under consideration are closer to the nominal significance levels than the overall size estimates of the our test, it can still be concluded from an examination of the power curves above that our test has slightly better power than Swanepoel and Van Wyk's test in all cases. With exception of the case in Figure 4.1, it has much better power than of Diggle and Fisher's test and in all cases it has considerably better power than Jenkin's test . In fact the power of Diggle and Fisher's test with exception of the case in Figure 4.1 tends to decrease instead of increasing at the one end and Jenkin's test has almost no
power. Simulations of Jenkins test using other windows, namely the Parzen and Bartlett windows, reveal similar estimates for power to those shown in Table 4.1.

Since is all of the above cases the series were simulated from autoregressive models and since our test involves fitting autoregressive models, it would be expected that the this test would generally perform better than the other tests. To remove this apparent unfair advantage our test has over the others, it was decided at this point to make the power comparisons for series simulated from moving average processes. Comparisons are made for the following situations: MA(1) $\theta=0$ versus MA(1) $\theta>0$ and MA(1) $\theta=0.5$ versus $\operatorname{MA}(1) \theta \neq 0.5$. The results of these simulations for $T=200$ for the tests six tests are shown in Tables A4.4 to A4.6. The power curves at the $5 \%$ of significance are shown in Figures 4.4 to 4.5 .

Figure 4.4 Power Curve for White Noise versus MA(1) $\theta=0$ versus $\theta>0$ (5\% level of significance)

Figure 4.5 Power Curve for MA(1) $\theta=0.5$ versus $\theta \neq 0.5$ ( $5 \%$ level of significance)

It can be seen from these power curves, that even though overall size is slightly overestimated, our test still performs better that the other tests. The test of Swanepoel and Van Wyk which performed nearly as well as our test in some cases earlier on, now performs quite poorly.

## 5 <br> APPLICATIONS

### 5.1 Loans Data

Total fixed loan commitments in thousands of dollars of all banks, finance companies and credit co-operative in Australia for the period January 1985 to November 1995 are examined. Of interest is whether there are significant differences in the lending patterns between the institutions. The natural log transformation of these series are shown in Figure 5.1. It can be seen that while lending is on different levels for the three institutions, the lending patterns over the given time period are similar for the banks and finance companies, but differ for the banks and credit cooperatives and for the finance companies and credit co-operatives. Because the series
are nonstationary, the series were transformed and differenced in an attempt to make them stationary. If was assumed that the first difference of the natural log transformation of each series was stationary. All further analysis was carried out on these series. Each of these series has 130 observations.

The test derived in Section 2 was first applied to all three series. The results are shown in Table 5.1 from where it can be seen that there is some residual correlation between the two series in each pair. Tests for correlation reveal that there is a significant correlation between the disturbances of the underlying the generating processes of the two series in each pair. This is to be expected since the same economic factors are expected to affect lending commitments from each type of institutions. From Table 5.1 it can be seen that there is a significant difference between the generating processes of the series since the p-value of the test is 0.0005 .

Multiple comparisons are then considered by performing the test for $q=2$ for every pair of series. The results of these multiple comparisons are shown in Table 5.2. from which, we make the following observations: The residual correlation between each pair of series is very similar to those obtained when the test was applied simultaneously to all three series. There is not enough evidence to conclude that the level of lending patterns between the banks and finance companies are significantly different but there is strong evidence to conclude that the level of lending patterns between the banks and credit cooperatives and between finance companies and credit cooperatives are significantly different. Since the levels of the undifferenced bank and finance companies series are clearly different, it is clear from the result of no significant difference between the underlying generating processes of the corresponding differenced series, that the test can distinguish between the underlying
stochastic nature of the two series but not the underlying deterministic nature of the two series.

The results of the multiple comparisons tests correspond with casual observations one could make from the examination of the series in Figure 5.1.

Table 5.1 $\quad$ Results of Loans Series Application for $\mathbf{q}=\mathbf{3}$

### 5.2 Tree Ring Data

In order to reconstruct historical climates based on information from trees, one type of measurement that climatologists use is distances between the consecutive rings of trees. Figures 5.2 to 5.4 show tree ring data series for three separate sites about 10 km . apart at about the same altitude on Mount Egmont on the North Island of New Zealand. Each series consists of 352 observations which are standardised distances between rings, averaged over a number of trees in a particular site. Standardisation allows samples with large differences in growth rates to be combined. It is also used to remove any undesired growth trends present. The residual correlations between the series of sites 1 and 2 and between the series of sites 1 and 3 are very low and tests for correlation reveal that there is no significant correlation between the disturbances of the generating processes of the two series in each pair. The residual correlation between the series of sites 2 and 3 is higher than the other two residual correlations and a test for correlation reveals that there is significant correlation between the disturbances of the underlying generating processes of these two series. Of interest is whether there are any significant differences between the growth pattern at the three sites given that climatic conditions would be assumed to be the same at the three sites.

The test is first applied to all three series. The results are shown in Table 5.3. The test gives a p-value of 0.4517 thus leading to the conclusion that there are no significant differences between the underlying processes of the three series. Even though there is no need to perform multiple comparisons tests, we nevertheless perform the test for two series at a time. These results are shown in Table 5.4. It can be seen that the residual correlations are similar to those obtained when the test is applied simultaneously to the three series. Furthermore the results of the test for two
series at a time reveal no significant differences between the generating processes of the series although the results for the comparison of sites 2 and 3 are fairly close to being significant at the $5 \%$ level of significance.

| Site 2 vs Site 3 | $\mathrm{AR}(8), \operatorname{AR}(3)$ | -0.1743 | 0.0698 |

## 6 <br> CONCLUDING REMARKS

From the simulation study is clear that for series of reasonable length, distributional approximations of our proposed test statistic to the chi-square distribution are reasonably adequate for both $\mathrm{q}=2$ and 3. The size of the test
reasonably approximates the nominal size. The test has reasonably good power and can be seen from the power comparisons in Section 4 it has better power for the case of two independent stationary series than the other tests under consideration. From the results in Section 5, it appears that the test can be quite successfully applied. Furthermore the advantage that our test has over the existing tests in the literature is that it can be applied to independent as well as related time series and it can also be applied to testing for significant differences between more than two stationary time series.

## ACKNOWLEDGMENTS

I am grateful to Dr. Brett Inder for his useful comments and technical support. I am also grateful to Prof. John Murphy of the Mathematics Department of Monash University for supplying the tree ring time series. The loans data were obtained from a publicly available database of the Australian Bureau of Statistics.
