Analysing adoption of soil conservation measures by farmers in Darjeeling district, India

C. Singha;

Hindu College, University of Delhi, Economics, India

Corresponding author email: chandan@econdse.org

Abstract:

The study assess the key determinants of the decision to adopt soil conservation in Teesta River Watershed, in Darjeeling District in the Eastern Himalayas. In this watershed, there have been soil conservation both by the individual farmers on their own farm and by the government at the sub-watershed level. We collected data through a primary survey conducted during 2013. This study explicitly accounts for possible neighbourhood effects in influencing adoption. This is captured both by identifying adoption practices among farmers who are immediately upstream, and using spatial econometrics that incorporate the spatial distance between neighboring farms. We use Bayesian formulation of a standard probit model in conjunction with Markov Chain Monte Carlo to estimate the model. The findings suggest positive evidence of neighbourhood impact on farmers in adoption decisions. We also examine if adoption decisions differ between farmers residing in treated and untreated sub-watershed and conclude that they do not.

Acknowledgment: I thank the South Asian Network for Development and Environmental Economics (SANDEE) for supporting the study financially. This study is part of my PhD dissertation at Department of Economics, Delhi School of Economics. ANALYSING ADOPTION OF SOIL CONSERVATION MEASURES BY FARMERS IN DARJEELING DISTRICT, INDIA

Abstract

The study assess the key determinants of the decision to adopt soil conservation in Teesta River Watershed, in Darjeeling District in the Eastern Himalayas. In this watershed, there have been soil conservation both by the individual farmers on their own farm and by the government at the sub-watershed level. We collected data through a primary survey conducted during 2013. This study explicitly accounts for possible neighbourhood effects in influencing adoption. This is captured both by identifying adoption practices among farmers who are immediately upstream, and using spatial econometrics that incorporate the spatial distance between neighboring farms. We use Bayesian formulation of a standard probit model in conjunction with Markov Chain Monte Carlo to estimate the model. The findings suggest positive evidence of neighbourhood impact on farmers in adoption decisions. We also examine if adoption decisions differ between farmers residing in treated and untreated sub-watershed and conclude that they do not.

1 Introduction

Soil erosion arising due to unsustainable land use patterns, especially in agriculture, forestry and urban development is a negative externality affecting a number of stake holders who depend on land, which is a scarce natural resource. First and foremost, Soil erosion contributes to loss of agricultural productivity affecting farmers. Viewed in a larger context, since agriculture is the major source of livelihood of people, particularly in developing countries, rapid soil erosion poses a threat to the food supplies and livelihoods of those involved in agriculture (Barbier, 1995). Moreover, beyond a certain threshold, soil erosion can make the process of regeneration of soil cover irreversible, and affect future food supplies and livelihoods. Therefore, the link between on-farm soil erosion and yield is both inter-generational and intra-generational. Degraded land affects other natural resources as well; for example, reduction in crop yields may force farmers to intensify deforestation (Lopez, 2002). Soil erosion also leads to significant negative externalities (Somanathan, 1991 and Mbaga-Semgalawe and Folmer, 2000). However, soil erosion can be limited, and the resulting top soil loss reduced, through proper on-site and off-site soil and water conservation measures.

To contain soil erosion farmers adopt various farm-level (on-site) measures, such as: terracing, contour practices, revegetation, crop mixture, fallow practices, land drainage system, agro-forestry and crop residue management (Scherr, 1999). These on-farm soil conservation measures provide benefits ranging from local (increased crop yields to farmers), regional (various off-site benefits such as flood control) to global level (climate change mitigation benefits through carbon sequestration), and can be both short-term and long-term in nature (Bouma et al., 2007). Given this context, this paper attempts to analyse the determinants of on-farm soil conservation practices in the mountainous Darjeeling district of West Bengal state, India. We model the primary drivers of farmers' decisions to adopt soil conservation.

A variety of factors influence a farmer's decision to adopt soil conservation measures. There is an incentive to adopt soil conservation if the discounted gain from the marginal increment of crop production is greater than the opportunity cost of forgone income (Moser and Barret, 2006). The random utility model provides the basis for consumer choices between competing alternatives of soil conservation practices, and has been widely used in the vast empirical literature examining the determinants of soil conservation decision of farmers. These studies suggest that the predominant socioeconomic determinants of farmers' adoption of soil conservation practices are membership in farmers' organizations, number of years of school

education of farmer (Sidibe, 2004), spouse's educational attainment, government assistance, household wealth, labour availability, market accessibility, extension service to the farmer (Teklewood et al., 2014), cash crop cultivation, perceived erosion level of the farm, farm size and a soil and water conservation programme (Mbaga-Semgalawa and Folmer, 2000) and existence of a formal credit market (Wossen et al., 2015). In addition, farm characteristics such as soil type, depth of soil, slope of the land and soil quality have a positive effect on the adoption of soil conservation practices (Teklewood et al., 2014).

A few studies introduced neighbourhood aspects into their analysis of the adoption of soil conservation practices in the literature of agricultural technology adoption. Battaglini et al. (2012) showed that there can be strategic substitutability (free-riding) or strategic complementarity with neighbours in investment in public goods, like soil conservation. There are two main strands of the literature on technology adoption or soil conservation that attempt to incorporate the interdependence of decisions. The first strand explicitly accounts for interactions with neighbours through models of social learning and networks (Mbaga-Semgalawa and Folmer, 2000; Conley and Udry, 2003; Bandiera and Rasul, 2006; Moser and Barret, 2006 and Teklewood et al., 2014). These studies follow Manski's (1993) observation that the "propensity of an individual to behave in a certain way changes with the behaviour of the individual's social group" (cited in Lapple and Kelley, 2015). The second strand attempts to capture the role of interaction on the decisions to adopt a given technology, by using techniques of spatial econometrics to model dependence either in the outcome variable (adoption) or in the error term, or both. The interaction is based on a measure of proximity that is typically geographical in nature. In the context of analysing the adoption of soil conservation practices, the use of spatial dependence framework is logical for many reasons.

First, soil conservation in one farm can assist or constrain it in adjacent farms. The assumption is that households located near each other exhibit similar behaviour; closer the household, more similar the behaviour (Holloway and Lapar, 2007).¹ The logic is rooted in Tobler's law: "Everything is related to everything else, but near things are more related than distant things" (Drukker, 2009). Factors such as inter-farm information flow, neighbourhood competition or

¹ "Such models deal with question of how the interaction between economic agents can lead to emergent collective behaviour and aggregate patterns, and they assign a central role to location, space and spatial interaction" (Anselin, 2002).

cooperation, geographical clustering of innovators, etc., could induce similar adoption behaviour in farmers (Abdulai and Huffman, 2005).

Second, soil conservation practices can be location-specific, with particular types of soil conservation practice more suitable for particular types of land. Agricultural productivity also depends on various localized factors, such as soil type and quality, ambient and soil moisture, ecosystem services, topography of land, and distance from the nearest stream (Colney, 1999). Similarity in all these factors may lead to similarity in farming and conservation practices (Pattanayak and Burty, 2005). These variables are often not measured, resulting in dependence in residuals, and thus spatial factors contribute indirectly to the observed adoption of soil conservation practices (Holloway and Lapar, 2007). Hence, it is important to model spatial dependence; otherwise, the estimated coefficients of the determinants of soil conservation practice can be biased. Generally, studies on technology adoption in agriculture like Pinkse and Slade, 1998; Colney, 1999; Holloway and Lapar 2007; Wang et al., 2013; Lapple and Kelly 2015 have used spatial dependence models, but it has not been used yet in studies on soil conservation. The present study adds to the literature of adoption of soil and water conservation practices by bringing the spatial aspect into the analysis of the adoption of soil conservation practices.

For the spatial correlation, we consider models of (a) spatial dependence in outcome, that is, adoption of soil conservation practice (the spatial lag model); (b) spatial dependence in the error terms of the decision equation (the spatial error model); and (c) a composite model that allows for both spatial dependences on outcome and errors following Anselin (2002), LeSage and Pace (2009) and others. We use the Bayesian formulation of a standard probit model in conjunction with the Markov Chain Monte Carlo (MCMC) method to estimate the parameters.

Besides the farm level soil conservation measure, many off-site measures exist; relevant for this study is the set of measures adopted for mountainous sub-watersheds by the Government to raise agricultural productivity. We call this set of measures as treatment. Watershed management can be effected at various scales, from the entire river basin to tiny upland watersheds. But most watershed development measures aim to manage smaller topographical units, like sub-watersheds as in our study area, rather than the entire river basin.² Farmers' decisions to adopt on-farm conservation practices can depend on the distribution of benefits of sub-watershed treatment, (Feder and Slade, 1985) making it necessary to consider sub-watershed treatment

² Food and Agriculture Organisation of the United Nation, <ftp://ftp.fao.org/docrep/fao/010/a1295e/a1295e07.pdf>, Aug 26/07/2015

status as one of the determinants of soil conservation practices. Hence, the present study also examines if farmers' adoption of soil conservation practices depends on whether the farmer resides in a treated sub-watershed or not, to understand if treatment at the sub-watershed level serves as a substitute of, or is complementary to, adoption.

We use primary data collected on the adoption of soil conservation practices during 2013 from the Teesta River Basin in Darjeeling district of India. The findings suggest a strong and positive evidence of neighbourhood impact (both upstream and spatial) on farmers in making soil conservation decisions. A higher proportion of adopters in the immediate upstream neighbourhood increases the probability of adoption. Also, we find that, among several competing spatial models, it is the spatial lag probit model that best describes our data. In particular, it performs better than a non-spatial probit model. A comparison of the marginal effects for the two models suggests that failing to control the spatial dependency in outcomes leads to over-estimation of the impact of other variables in the adoption decision. The findings also suggest that there is neither substitution nor complementarity between sub-watershed treatment and adoption at the farmer level. Capturing spatial dependency is, thus, important from the policy perspective. Knowledge of the magnitude and extent of spatial dependency can help the government and other organizations in designing better policies to promote the adoption of soil conservation practices at a lower cost.

The organisation of this study is as follows: Section 2 briefly discusses study area and soil conservation measures. Section 3 discusses the spatial dimension of soil conservation, which includes the conceptual framework, model specification and section 4 outlines method of estimation. Section 5 interprets the coefficients of different spatial models. Section 6 describes the data and the definition of variables. Section 7 discusses and compares the results of spatial and non-spatial analysis. Lastly, Section 8 concludes the discussion and describes the policy implications.

2 Study Area and Soil Conservation Measures

This study considers a case study of one of the most soil erosion affected river basins in India, the Teesta River Basin in Darjeeling district of West Bengal state examines various ongoing and potential initiatives undertaken by farmers and government in the river basin. The presence of varying property rights to land in the river basin requires differential actions by different land owning agents. Essentially there are two property rights regimes identified in the basin: private

property and government property. Private property is in the form of farms of land owned by farmers in the downstream and government property is the forest land owned by government upstream. It is observed that both farmer groups and Government undertake soil conservation methods in the basin. Farmers have adopted number of on-farm soil conservation measures while Government of India has initiated soil conservation programme at sub-watershed levels in the name of Teesta River Valley Programme (TRVP) for Soil Conservation (Singha, 2016).

The on-farm soil conservation measures adopted by farmers are: contour bunding, afforestation, bamboo plantation, orchard plantation, terracing, tree belt, broom plantation and grass stripping (Singha, 2017). The ongoing Teesta River Valley Programme, which was implemented by the State Forest Department since 1977, introduced several off-site measures, including afforestation, broom/fodder cultivation, orchard plantation, belly benching and stream bank control to avoid landslides (by reducing the force of water through engineering construction and vegetation to minimize the removal of soil particles of the site), construction of catch water drains (which divert the water flow and reduce soil erosion),³ and slip control/stabilization (i.e., technical measures to mitigate landslides) (National Land Use and Soil Conservation Board, 1992; Kurseong Soil Conservation Division, 2011; Kalimpong Soil Conservation Division, 2010).

3 Conceptual Framework: Accounting for the Spatial Nature of Adoption Decisions

We adapt the framework provided by Ballester et al. (2006) and Jackson (2008) to understand a household's decision to invest in soil conservation measures. We assume that farmers have full information about soil conservation practices adopted by their neighbours. Let there be n number of farmers, and let $e_i \in R_+$ represent the effort level of farmer i , where $i=1, 2, \dots, n$, expended to adopt soil conservation practices. We also assume that the payoff function of farmer i is a quadratic function of the effort:

$$U_i(e_i, e_{-i}) = a_i e_i - \frac{b_i}{2} e_i^2 + \sum_{j \neq i} w_{ij} e_i e_j \quad (1)$$

The first two terms in the above equation is the standard utility of own effort e_i , where $a_i = a \geq 0$ and $b_i = b > 0$ for all $i = 1, 2, 3, \dots, n$ are scalars. Too much effort is not warranted, since it diminishes the payoff at the margin, which is captured by the second term of equation (1). That is, equation (1) is concave in own effort, since $\frac{\partial^2 U_i}{\partial e_i^2} = -b < 0$. e_{-i} is the sum of the efforts of

³ Unabridged Dictionary, <http://www.merriam-webster.com/dictionary/catchwater>, October 23, 2015.

others, i.e., the combined effort of neighbours, and w_{ij} is the weight that farmer i puts on his neighbour j . The last term represents the network effect in the neighbourhood, i.e., it captures the utility from a bilateral interaction, $\frac{\partial^2 U_i}{\partial e_i \partial e_j} = w_{ij}$, where $i \neq j$. If an increase in the effort level of j raises the effort level of i , then $w_{ij} > 0$ represents strategic complementarity. On the other hand, if an increase in the effort level of j diminishes the effort level of i , then $w_{ij} < 0$ and implies strategic substitution.

The best response of the farmer given the level of efforts by others is obtained by using the first order condition (i.e. differentiating with respect to own effort):

$$e_i = \frac{a}{b} + \sum \frac{w_{ij}}{b} e_j \quad (2)$$

The above expression suggests interdependence of efforts between farmers and their neighbours; this can arise from localized factors (like “neighbourhood effect, copy-cattng, peer group effect, strategic interaction, etc.” (Anselin, 2002)) and from diffusion of knowledge. Equation (2) can also be written in matrix form:

$$\begin{pmatrix} e_1 \\ \vdots \\ e_n \end{pmatrix} = \begin{pmatrix} a/b \\ \vdots \\ a/b \end{pmatrix} + \frac{1}{b} \begin{pmatrix} w_{11} & \cdots & w_{1n} \\ \vdots & \ddots & \vdots \\ w_{n1} & \cdots & w_{nn} \end{pmatrix} \begin{pmatrix} e_1 \\ \vdots \\ e_n \end{pmatrix} \quad (3)$$

$$\text{or } e = \beta_0 + de \quad (3a)$$

$$\text{or } e = (I - d)^{-1} \beta_0 \quad (3b)$$

where I is the identity matrix, $\beta_0 = \left(\frac{a}{b}, \frac{a}{b}, \dots, \dots, \frac{a}{b}\right)'$ and $d = \frac{1}{b} \begin{pmatrix} w_{11} & \cdots & w_{1n} \\ \vdots & \ddots & \vdots \\ w_{n1} & \cdots & w_{nn} \end{pmatrix}$. A stable equilibrium exists if the matrix $(I - d)$ is invertible. The matrix implies $(n^2 - n)$ possible relations between n observations, and since diagonal elements represent weights on the farmer i 's own effort, they are all zero (LeSage and Pace, 2009).

3.1 Spatial Lag Model

We extend the above model (3a) by adding potential conditioning variables and distinguishing latent effort from observed effort. The empirical specification for the estimation of equation (3a) is as follows:

$$e^* = \rho W e^* + X\beta + u \quad (4)$$

where, e^* is a vector of latent effort. In this case, e^* is not observed but is present in the effort function of our representative farmer. In other words, as before, the unobserved effort of the neighbourhood firms e_{-i}^* influence e_i^* (Anselin, 2002). As mentioned in Section 1, the dependence in latent effort arises due to the flow of information among the farmers, and due to the competition or cooperation between them. We include X , which is a $(n \times k+1)$ matrix of other exogenous variables of household and farm characteristics (defined in Section 4), and $\rho = 1/b$ is the spatial autoregressive parameter (scalar), that is additional to any standard latent variable model. β is $(k +1 \times 1)$ vector of parameters and u is a random shock with $E(u) = 0, E(uu') = \sigma_u^2 I_n$.

If $\rho=0$, that is, there is no spatial dependence then equation (4) becomes:

$$e^* = X\beta + u \quad (5)$$

Equation (5) can be analysed using a standard (non-spatial) binary probit model. In a real world situation, we cannot observe the quantum of effort that farmers put into soil conservation. The standard way to model this is to assume that an action e is observed whenever the underlying latent variable e^* meets a condition: for example, e is observed when $e^* > 0$. Thus,

$$e_i = \begin{cases} 1 & \text{if } U_i(e^*) > 0 \\ 0 & \text{if } U_i(e^*) \leq 0 \end{cases} \quad (6)$$

where $U_i(e^*)$ is the payoff from latent effort e^* .

From equation (6), we can get the conditional density function of effort given the exogenous variables:

$$\Pr(e_i = 1 | X) = \Phi_i(X\beta) \quad (7)$$

where Φ_i is the cumulative normal distribution function, given the assumption that u is normally distributed (Wang et al., 2013).

In case $\rho \neq 0$, the above equation (4) is known as spatial reaction function (Bruckner 2003), and is also called spatial lag model or spatial autocorrelation model. Through the above specification, this study models how the latent magnitude of effort of soil conservation at a farm (e^*) is determined by the latent magnitude of effort of soil conservation in neighbourhood farm, $\rho W e^*$ (Anselin, 2002) and by various exogenous household and farm characteristics, $X\beta$. Assuming $(I - \rho W)$ is non-singular, equation (4) implies:

$$e^* = (I - \rho W)^{-1} X \beta + \varepsilon \quad (8)$$

where

$$\varepsilon = (I - \rho W)^{-1} u \quad (9)$$

As before, since e^* is not observed, we use a discrete variable e_i to define if a given farmer adopts soil conservation measures or does not.

In this case, it can be shown that

$$\Pr(e_i = 1) = \Pr[\varepsilon_i < h_i(X, W, \beta, \rho)] \quad (10)$$

where h_i is the multivariate normal density function (Anselin, 2002), following the assumption of normality of u . The variance-covariance matrix of ε is as follows:

$$E(\varepsilon \varepsilon') = (I_n - \rho W)^{-1} (I_n - \rho W')^{-1} \sigma_u^2 \quad (11)$$

3.2 Spatial Error Model

Thus far, we have considered spatial dependence in soil conservation practices. There can also be dependency in unobserved factors. As mentioned in Section 1, this type of dependency arises due to many geographical and economic factors that remain unmeasured or unobserved, that may influence the adoption of soil conservation practices and are correlated over space. Similar unobserved characteristics may lead to a similar level of effort in soil conservation; neighbouring farmers are more likely to face similar soil, topographic and climatic conditions than more distant farmers. In this case, we model only dependency of residuals, instead of dependence in the latent effort of soil conservation practice, and assume further that these unobserved factors are not correlated with the exogenous variables. Then, equation (4) can be modified as:

$$e^* = X \delta + v \quad (12)$$

where, $v = \gamma W v + z$

and, $E(z) = 0, E(z z') = \sigma_z^2 I_n$

or, $v = (I - \gamma W)^{-1} z$

Instead of exhibiting spatial dependency on outcome, the above equation (12) exhibits spatial dependency on the error term, and is termed spatial error model (LeSage and Pace, 2009).

Analogous to equation (10), what is observed is a binary outcome, and the probability of adoption is given by:

$$\Pr(e_i = 1) = \Pr[v_i < h_i(X, W, \delta, \gamma)] \quad (13)$$

where h_i is the multivariate normal density function. The variance-covariance matrix of v is as follows:

$$E(vv') = \sigma_z^2(I_n - \gamma W)^{-1}(I_n - \gamma W')^{-1} \quad (14)$$

3.3 General Spatial Autocorrelation Model

A model that incorporates spatial dependence in both outcome as well as errors is known as the general spatial autocorrelation model (SAC model) (LeSage and Pace, 2009) and can be written as follows:

$$e^* = (I - \rho W)^{-1}X\theta + \tau \quad (15)$$

where, $\tau = (I - \rho W)^{-1}(I - \gamma W)^{-1}\varphi$

and, $E(\varphi) = 0, E(\varphi\varphi') = \sigma_\varphi^2 I_n$

Similarly, like the spatial lag and spatial error models, as in equations (8) and (13), the probability of adoption can be explained as:

$$\Pr(e_i = 1) = \Pr[\tau_i < h_i(X, W, \theta, \rho, \gamma)] \quad (16)$$

where h_i is the multivariate normal density function with the variance-covariance matrix of τ is as follows:

$$E(\tau\tau') = (I_n - \rho W)^{-1}(I_n - \rho W')^{-1}(I_n - \gamma W)^{-1}(I_n - \gamma W')^{-1}\sigma_\varphi^2 \quad (17)$$

4 Method of Estimation

The method of estimation of the spatial lag model must account for the fact that the covariance structure (11) makes the marginal distribution of ε_i heteroscedastic (Anselin, 2002). As a result, the estimators of standard probit model are inefficient. In addition, ε_i are not independent and identically distributed due to spatial correlation. As a result, the likelihood function involves multidimensional integration, which is computationally intensive (Wang et al., 2013). This study uses the Bayesian method in conjunction with the MCMC method to estimate the spatial probit

model, following LeSage and Pace (2009). See Online Appendix 1 for the detailed discussion of method of estimation.

5 Interpretation of Coefficients of Spatial Models

The interpretation of marginal effects with spatial probit models is quite different from that of marginal effects under standard probit models. For instance, in a spatial lag model, a change in the explanatory variable of i th farmer has an effect not only on the soil conservation practices of the i th farmer e_i but also on those of other farmers e_j , $i \neq j$. This means that a change in the k^{th} variable of i^{th} farmer, x_{ki} , will affect the expected probability of adoption of his own and others' soil conservation practices. The marginal effect of the non-spatial probit model is given by:

$$\frac{\partial E[e | x_k]}{\partial x_k} = \Phi(x_k \beta_k) \beta_k \quad (18)$$

In contrast, the marginal effect of the spatial probit model is given by

$$\frac{\partial E[e | x_k]}{\partial x_k} = \Phi(H^{-1} I_n \bar{x}_k \beta_k) \odot H^{-1} I_n \beta_k \quad (19)$$

Where \odot is the Kronecker product,

$$H = (I_n - \rho W) \quad (20)$$

The diagonal element of expression (19) above represents the direct effect, which is like the marginal effect of the non-spatial probit model. But in this model, there are feedback effects as well—as a change in e_i from a x_{ki} also influences e_j which, in turn, affects e_i . Also, there is a cumulative effect of changes in x_{kj} where $i \neq j$ on e_i . The off-diagonal elements represent indirect effects. It is common to refer to the row sums as the “total effect to an observation”: it is the impact on e_i from changing the k^{th} explanatory variable in the specified neighbourhood. The average direct effect is taken over all diagonal elements, while the average indirect effect is the difference between average total effect and average direct effect. By symmetry, the row sums and column sums are the same. The difference between the total effect and the direct effect represents the indirect effect.

In our case, the direct effect is the change in the probability of soil conservation practices of the i^{th} farmer, because of a minute change in an explanatory variable of the same farmer, that is, x_{ki} . On the other hand, the indirect effect is the change in the probability of adoption of soil conservation practice of farmer i due to the feedback effects from farmer j in the

neighbourhood, i.e., the cumulative effect. The effect of the soil conservation practices of the neighbouring farm depends on physical proximity, which is captured by the spatial weight matrix and the spatial autocorrelation parameter.

The spatial error model does not contain the spatial lag explanatory variables or the outcome variable. Therefore, the interpretation of marginal effect is similar to that in the non-spatial probit model. In the general SAC model, the marginal effect takes a similar form as in expression (19), since the spatial lag error does not come into play when considering the $\frac{\partial E[e | x_k]}{\partial x'_k}$. Therefore, the interpretation of marginal effects is similar to that in the spatial lag model (LeSage and Pace, 2009).

6 Data and Variable Definitions

The data for this study was collected through a primary survey conducted during 2013 in Darjeeling district of Teesta River Valley of Eastern Himalaya in India (please refer to Singha, (2017) for detailed description of survey design).

6.1 Spatial Weight Matrix

All the farms in the survey were geo-coded, and the software package Matlab was used to calculate the Euclidean distance between all the farms. We use this information to generate the different types of spatial weight matrix suitable for our analysis.

Given the context of adoption, we specify the spatial weight matrix W using neighbouring farmers who live within a specified distance. For a sample of n farmers, we specify W to be an $(n \times n)$ matrix defined as the inverse of the Euclidean distance between neighbours. This assigns higher weights to nearby farmers than to relatively distant farmers. We try various specifications, varying the distance within which spatial dependency is assumed to play a role. In all specifications, $W_{ii} = 0$ and the matrix is symmetric and row-standardized, i.e., the row sum is

bounded uniformly to 1. We implemented row-standardization as $W_{ij} = \frac{1/d_{ij}}{\sum_{j=1}^n d_{ij}}$, where $d_{ij} =$

Euclidean distance between two farmers.

In another variant, the spatial weight matrix WC is specified as a contiguity matrix (Anselin, 2002), which assumes all the farmers within a village can be deemed to be neighbours and affect each other's decision. That is, $WC_{ii} = 1$ within a village but $WC_{ii} = 0$ outside the village. We implement row-standardization by dividing all the elements of a row i by number of non-zero

entry of the row. Since our sample consists of 12 farmers from each village, this means that each farmer in our sample has 11 neighbours within a village. If we allow spatial dependency to prevail within a village as well as within the nearest village in our sample, the weight matrix consists of 23 neighbours in *WC1*. In similar fashion, the spatial dependency confined to the nearest two and three villages in our sample allows the weight matrix to pick 35 neighbours in *WC2* and 47 neighbours in *WC3* respectively.

6.2 Dependent Variable: Determining Adoption

The different types of soil conservation measures used by farmers include contour wall/contour bunding, afforestation, bamboo plantation, orchard plantation, tree belt, terracing, broom cultivation and grass stripping. This list is exhaustive but not mutually exclusive.⁴ We specify adopters as those who have adopted at least two measures from contour bunding, afforestation and bamboo plantation. Table 1 suggests that 49 percent of the farmers have adopted at least two measures. We define these farmers as adopters. As a robustness check, we include a different measure of adoption, as noted later.

Table 1 here

6.3 Explanatory Variables

Adoption of soil conservation practices depends on a number of factors, such as the socioeconomic characteristics of the farmer/farming households, farm characteristics, measures of market access and information of soil conservation in immediate upstream neighbourhood. We present the description and summary statistics of in Table 2. The detailed description of the explanatory variables of socioeconomic characteristics, farm characteristics and measures of market access are given in Online Appendix 2.

Table 2 here

⁴ During the pilot survey, we also asked the respondents to rank each soil conservation measure by its effectiveness in tackling soil erosion on a scale of 1 to 10. By calculating the average, we worked out that the soil conservation practices considered most effective are stone terracing, stone/contour bunding, afforestation (plantation of woody perennial), bamboo plantation and terracing. Only a few used stone terracing; therefore, we exclude this soil conservation practice. Moreover, 90 percent of the farmer reported to adopt terracing as soil conservation measure. We consider terracing as “no conservation measure”. However, we did not look into intensity of these measures.

6.3.1 Information of Soil Conservation in Immediate Upstream Neighbourhood

For each respondent farmer, this study elicited information on the soil conservation practices adopted on the nine nearest upstream farms. The existence of intensive soil conservation activity in the neighbourhood may have significant complementary or substitution effects on the conservation decision (Battaglini et al., 2012). Figure 1 presents the rate of adoption of the respondent farmer, conditional on information on proportion of adoption in immediate upstream neighbourhood. We find that when less than 10 percent of neighbours adopt contour bunding, then adoption of contour bunding as soil conservation technique on own farm is 10 percent. Similarly, when the rate of adoption of contour bunding in the neighbourhood is over 70 percent, then 72 percent of the respondents also use a contour bunding. This suggests that there may be significant complementarities between information of upstream adoption and sample farmer adoption. Similarly, when the proportion of adoption of afforestation lies between 10–30 percent in the immediate upstream neighbourhood, then 54–55 percent of the respondent farmers adopt afforestation. If the proportion of immediate upstream neighbourhood adoption of afforestation is over 50 percent, then the adoption rate among respondent farmers is around 80 percent. Therefore, a particular adoption measure is lower when its adoption measure is lower in the immediate upstream neighbourhood; the converse is also true.

Figure 1 here

6.3.2 Sub-watershed and Village Characteristics

The study uses three dummy variables to capture sub-watershed characteristics that may impact the soil conservation decision. The first dummy captures whether the sub-watershed was treated under the TRVP or not, and the second captures whether the sub-watershed belongs to the very high erosion prone category or not. In the study, many villages are situated in or near the frontier of forest areas (forest village). Residents of these villages lack exclusive property rights over land; this lack may, therefore, act as a disincentive from investing in soil conservation. We use a third dummy variable for forest villages.

7 Results from Different Models

7.1 Estimated Coefficients from Non-spatial Analysis

We first estimate a probit model of adoption that does not incorporate any spatial dimensions, using the variables as discussed in Section 6.3 above and Online Appendix 2. This serves as a

benchmark for the results of the various spatial probit models. We also include the interactions between soil conservation practices in the neighbourhoods upstream.⁵

The estimated marginal effects (using equation 20 in Section 4.1 above) are presented in Table 3, along with heteroscedastic-consistent robust standard errors. They suggest that information on proportion of immediate upstream neighbours practicing contour, afforestation and bamboo plantation are significant. We conduct a Wald Test (Cameron and Trivedi, 2005) to check if the coefficients of the interaction terms of information on soil conservation practices in the immediate upstream neighbourhood are jointly and significantly different from zero. We find that they are, which suggests that the interaction between soil conservation practices in neighbourhoods immediately upstream affects a farm's adoption of soil conservation practices. Other significant variables include distance to the nearest local market, farm size, household size, soil stoniness and altitude of the farm in meters and dummies for very high soil erosion prone sub-watershed and for sub-watershed treatment.

Table 3 here

However, the analysis above has a limitation: as the estimation so far limits the neighbourhood to only the nine farm farms immediately upstream, the non-spatial probit model may provide only limited information on the interaction in adoption behaviour. The strategic interaction may prevail even outside the immediate upstream neighbourhood, and within the village or outside it. Importantly, the presence of any sort of spatial pattern in outcome, or error, or both outcome and error, may provide a biased marginal effect of the explanatory variables.

7.2 Spatial Analysis

We estimate three sets of spatial models—spatial lag model (equation 8), spatial error model (equation 12) and general spatial autocorrelation model (equation 15)—and present the resulting estimates of spatial correlation parameters ρ (outcome) and λ (error) in Table 4 for a range of specifications of the spatial weighting matrix, including the inverse distance spatial weight matrix (W) and the contiguity matrix (WC).

Table 4 here

⁵ We have three specifications for the non-spatial probit model: Models 1, 2 and 3. We conduct a likelihood ratio test to find out which of the three alternative models best suit the data, and find Model 1 best suited. The marginal effects of Models 2 and 3 are given in Online Appendix Table 1.

Note that for all variants of spatial weight matrix, the estimated posterior mean of ρ of the spatial lag model and the estimated posterior mean of γ of the spatial error model are statistically significantly different from zero. This justifies the use of spatial probit models rather than of the non-spatial probit model, and suggests that farmers within the specified neighbourhood are spatially dependent. This spatial dependency is due to dependency in adoption and/or in unobserved factors. However, when spatial dependence in both outcome and error are modelled together through estimation of the general spatial autocorrelation model, then the estimated spatial correlation on outcome, that is posterior mean of ρ remains significant but estimated spatial correlation on error, which is posterior mean of λ is insignificant across all the distance decay spatial weight matrices. Similarly, when we use contiguity matrix as spatial weight matrix, the spatial lag estimator (ρ) of the general spatial autocorrelation model for neighbourhood within a village and nearest village is significant, but the estimated λ is not significant.⁶

Taken together, the results from three different spatial models suggest that the spatial lag model best describes our data, and is therefore used for further analysis. The significance of the spatial parameter suggests that a farmer's adoption of soil conservation practices positively influences neighbouring farmers' adoption decision. This still leaves the question of which of the various spatial weight matrices W to use. To select one, we compare the posterior probabilities of adoption (equation 18) of five different weight matrices of the spatial lag model (Table 5). From the magnitudes, it appears that using an inverse weight matrix up to neighbourhood cut-off three kilometres is the best fit for spatial analysis, as it has the highest posterior probability.

Table 5 here

On the basis of these results, this study estimates and analyses a spatial lag model with an inverse distance matrix up to three kilometres as the spatial weight matrix. Since the posterior probability of the spatial lag model for within village contiguity matrix is 0.26, which is not much smaller than 0.27, we also estimate the spatial lag model with for within village contiguity matrix.

7.3 Results of Spatial Lag Probit

Using the same set of covariates as used in Model 1 of non-spatial analysis of the adoption decision, estimates from a spatial lag model using a neighbourhood defined as extending up to

⁶ We tried spatial models on several distance decay and contiguity matrices but presented few to avoid repetition.

three kilometres radius (inverse distance matrix) are reported in Table 6.⁷ The table presents direct, indirect and total effects, as explained in equation 21, along with 95 percent confidence intervals. As mentioned in Section 4.1, the direct effects are the diagonal element of equation (19), which captures the change in the probability of adoption of the i th farmer due to a small change in the explanatory variable of the same farmer, and has a similar interpretation as the marginal effect in a non-spatial probit model.

Table 6 here

All the coefficients of household characteristics have 90 percent confidence intervals that include zero (apart from the coefficient for the household size). The direct effect of the household size is 0.02, that is, an increase of 1 member of farmer i 's household increases farmer i 's probability of adoption by 0.02. The indirect effect of the same variable is 0.03, that is, the probability of adoption by farmer i due to an increase in 1 household member in the family of the neighbourhood of farmer i increases by 0.03. However, the 90 percent confidence interval of indirect effect of this variable includes zero. It implies that spatial spill over effect of family size on adoption is not credible. The total impact of the variable, therefore is 0.05; this variable was significant in the non-spatial analysis too. This finding is in line with previous studies such as Teklewood et al., 2014. This positive relationship between the household size and probability of adoption intuitively may be due to adoption measures are labour intensive. Larger household can devote more labour for soil conservation irrespective of the age composition within a household. However, proportion of household members between ages 14 to 65 is neither significant in spatial model nor in non-spatial model.

The total area of the farm, which is part of the farmer's asset holding, has the expected positive sign in the spatial lag model. More specifically, with the increase of every additional acre in the farm area of farmer i , the probability of farmer i 's adoption of soil conservation practices increases by 0.04. Intuitively, it implies household with larger farm area are more likely to devote resource or take away land out of cultivation for adoption. The adoption measure such as afforestation and bamboo plantation can be seen as diversification of farm production activity. The study such as Pope and Prescott (1980) suggests positive association between farm production diversification and farm size. The indirect effect of the farm area is 0.07, and its total effect is 0.11. The 90 percent confidence interval of indirect effect of farm area does not include zero, implying a significant

⁷ In this inverse distance weight matrix, the absolute log likelihood value is highest in Model 1, and justifies its selection over Models 2 and 3 even in spatial analysis like non-spatial analysis.

cumulative effect of neighbours' farm size on probability of adoption. Farm size in the neighbourhood is also associated with asset holding in the neighbourhood. Therefore, larger farm size in the neighbourhood can help the farmer to access informal credit, remittance and/or participate as agricultural labour. These factors can have cumulative positive effect on probability of adoption of soil conservation. None of the other farm characteristics has a significant impact in the spatial lag model. This is contrary to the findings of Bekele and Drake (2003) and of Wossen et al. (2015). This is also in contradiction to the finding of the non-spatial probit model of this study, where soil stoniness negatively affects adoption.

In non-spatial probit analysis, market access variables (such as distance to the nearest market and all-weather road) have a negative marginal effect (though small). Similar results are found in the study of Teklewood et al. (2014), though its marginal effects are larger than in this study. Our hypothesis about the transaction cost was negative impact on probability of adoption. Since distance to the market is supposed to impose added transaction cost on farmer to hire/purchase inputs (such as stone, sapling, labour etc.) and sell output (such as wood, fodder, bamboo etc.) of adoption measure. However, in the spatial lag probit model, these variables have no effects on adoption. Since significant mass of 90 percent interval straddling the origin. The explanation for non-significant effect may relate to the fact that farmers have access of inputs through local network. At the same time they use wood, fodder bamboo etc. for self-consumption and/or selling in or around nearby neighbourhood.

Information on upstream neighbours' adoption of soil conservation measures positively affects the probability of on-farm adoption. This is similar to the results from the non-spatial probit model. The information of proportion of neighbours immediately upstream that practise contour bunding, afforestation and bamboo plantation significantly and positively impact adoption. The indirect effect is, 0.28, while the direct effect is 0.17. This suggests that for every percentage point increase in the information of adoption of contour by immediate upstream neighbours of farmer j (farmer i 's neighbour), farmer i 's probability of adoption increases by 0.28 points. The significant indirect effect of this explanatory variable indicates that farmer i 's adoption decision is influenced by the information on adoption decision of not only his own immediate upstream neighbours but also by that of the immediate upstream neighbours of any other farmer j , in the radius of three kilometres. The total effect of information on proportion of immediate neighbour in upstream practising contour is, thus, 0.45. The direct, indirect and total effects of the information of proportion of immediate upstream neighbour adopting afforestation are 0.23, 0.41 and 0.64 respectively. Again, the direct, indirect and total effect of information on proportion of

immediate upstream neighbour practising of practising bamboo plantation together are 0.16, 0.27 and 0.43, respectively. The significance of the direct effect on suggests that neighbourhood effects are important and positively impact adoption. Also important is the positive indirect effect, as it provides empirical evidence that adoption of soil conservation practice is not limited only to the immediate upstream but is diffused over the entire specified neighbourhood (radius up to three kilometres), and that farmers communicate with each other (Lapple and Kelly, 2015). The information on joint adoption of afforestation and bamboo plantation affects adoption negatively in terms of direct, indirect and total effect. The same variable had an insignificant marginal impact in non-spatial probit. On the contrary, the joint adoption of contour and afforestation has a negative marginal impact on adoption in the non-spatial probit model, but an insignificant impact in the spatial lag probit model.

As far as sub-watershed and village level variables are concerned, the coefficients associated with the dummy for sub-watershed of very/high soil erosion prone category and treatment status of sub-watershed have positive and negative marginal impact under non-spatial probit, respectively. However, both these variables have insignificant effects in spatial analysis. The major point emerges that sub-watershed treatment neither discourages farmers from adopting soil conservation practices at their farms nor encourages them to do so.

A comparison of the coefficients representing the direct effect of the spatial probit model and the marginal effect of the non-spatial probit model suggests major differences. The effect of farm area on the probability of adoption experiences a decline by 33 percent in the spatial model compared to the non-spatial model. Similarly, the effect of information proportion of upstream neighbours practising contour bunding, afforestation and bamboo plantation on probability of adoption is reduced by 48 percent, 46 percent and 4 percent, respectively, in the spatial model. The differences in the magnitudes of the marginal effects suggests that considering only a probit model that does not account for spatial dependence in outcomes likely results in biased estimates.

To assess if these coefficients differ if one uses the spatial contiguity matrix instead, the corresponding direct, indirect and total effects estimated from the spatial lag probit using a within-village contiguity matrix are presented in Online Appendix Table 2. So far, in our discussion, we have defined as adopters those farmers who adopted at least two practices of contour bunding, afforestation and bamboo plantation. Now, we change the definition of adopters to those farmers who adopted bamboo plantation and afforestation, and of non-adopters to those farmers who adopted bamboo and broom plantation. In this categorisation, we are left with 315

observations. However, the posterior mean of spatial lag parameter (ρ) for spatial lag model is still significant, and it is 0.46 for spatial lag probit with neighbourhood cut-off up to three kilometres. The significance of posterior mean of spatial lag parameter suggests that the spatial dependence of soil conservation measure is robust. The direct, indirect and total effects of this spatial lag model are presented in Online Appendix Table 3.

8 Conclusion, Policy Implication and direction for Future Research

This paper analysed the determinants of on-farm soil conservation practices in a watershed in the Eastern Himalayas in India. To do so, it considered neighbourhood effects to be crucial in the decision to adopt, given that soil conservation is location-specific, where “location” extends beyond an individual farm. Accounting for the role of spatial dependence is important for two reasons. First, soil conservation in one farm can assist or constrain it in adjacent farms, due to strategic interaction. Second, many unobserved factors, like local amenities, contribute to adoption. The presence of the first factor results in spatial dependency in conservation practices, and of the second factor in spatial dependency in error. In doing so, it also explicitly accounted for if a sub-watershed treatment by the Government had any bearing impact on on-farm soil conservation measure. We applied a model of spatial lag probit model (following Anselin (2002); LeSage and Pace (2009); and others) that allows us to capture neighbours’ influence on outcome (i.e., the adoption decision). The model choice was motivated by the fact that—once we allow for spatial dependence in outcome—the spatial dependence in error is no longer significant. We defined neighbours as geographic neighbours, both within the village and up to a distance of three kilometres. We used the Bayesian formulation of a standard probit model in conjunction with the MCMC to estimate the parameters. We also compared the estimators of spatial and non-spatial probit.

The main finding, is that farmers located in close proximity (neighbours immediately upstream and within the sub-watershed) exhibit similar adoption behaviour; and that adoption of soil conservation measures is spatially interdependent. Spatial dependence in outcomes is important even after controlling for information on adoption behaviour in the immediate neighbourhood. Thus, models based on the non-spatial probit model are likely to yield biased estimates of the influence of key covariates in increasing adoption of on-farm soil conservation measures. Another important aspect of the spatial autocorrelation model is the explanation of marginal effects. The marginal effect of this model assesses both direct and indirect effects. It implies how changes in the value of an independent variable of farmer i influence his own soil conservation

practices (direct effect), and how a small change in an independent variable of farmer j in the neighbourhood influences farmer i 's decision to adopt soil conservation practices (indirect effect).

The study finds that household and farm characteristics are less important in adoption of soil conservation practices. The findings from the spatial lag probit suggest that sub-watershed treatment neither encourages farmers to adopt soil conservation practices nor discourages them from adopting these. It suggests that government investment in sub-watershed does not have any impact on private adoption at the farm. At the same time, the significance of the spatial parameter provides new avenues to influence adoption of soil conservation among farmers. Despite the change in spatial weight matrix, and the categorisation of adopters and non-adopters of soil conservation measures, these two broad findings remain significant.

The findings of the study may have relevance for policy makers. Given that the Himalayan mountains are one of the 34 biodiversity hotspots worldwide, and that agriculture is one of the major drivers of deforestation in the Himalayas, avenues like neighbourhood influence on the adoption of soil conservation practices may be usefully exploited to promote soil conservation measures. It may be useful to invest in geographically-intensive information programmes for sustainable agricultural practices. For example, agricultural extension workers can target small group farmers in a village to provide relevant assistance (like technical knowhow, training and financial support) for suitable soil conservation (suitable for a particular agro climatic condition) which will then get diffused taking advantage of strategic interaction. In our survey the respondents reported that agricultural extension service is absent in the region. Therefore, the findings of this study can lead to an alternative incentive mechanism rather than relying on the existing centralised top-down approach to encourage farm level investment in soil conservation.

There are several directions in which the research conducted in this study can be extended. The first is to track these farmers over time, and to construct a panel data set. This could help understand the timing of adoption decisions in general, of specific measures in particular; adoption decisions are undertaken gradually over time. Therefore, the non-adopter category of farmers in the present study includes both probable future adopters and never-adopters, and the adopter category includes recent adopters and long-time adopters. There could also be disadoption of soil conservation technologies in future. Understanding these dynamics and their implications is possible only through a panel study. Second, this study has used a narrow definition of neighbourhood, defined in term of physical proximity, that is, spatial distance.

However, “neighbourhood” can also be defined in terms of socioeconomic, cultural and physical proximity and kinship ties. The role played by strategic interaction defined in these terms in determining adoption could be considered in further research.

Online Appendices

Online Appendix 1: Method of Estimation

The posterior probability of $P(C | \omega)$ from Bayes' Rule is given by:

$$P(C | \omega) \propto P(\omega | C)P(C) \quad (A1)$$

where C is the model parameter, $P(\omega | C)$ is the likelihood, $P(C)$ is prior distribution and $P(\omega)$ is the data distribution.

In the MCMC, the posterior distribution of equation (A1) is decomposed into a sequence of conditional distribution of parameters instead of operating with posterior distribution. This method sequentially samples each parameter from their conditional distribution. It is based on the proposition that a large sample from these sets of conditional distributions for all parameters can approximate the form of the probability density function by deploying Kernel density estimators or histograms (LeSage and Pace, 2009). As a result, the MCMC approach does not rely on the asymptotic properties to determine valid standard errors (Lapple and Kelley, 2015).

The parameters in C are of two types:

1. parameters such as β and σ_u , where the form of conditional distributions are known; and
2. parameter such as ρ , where the form of conditional distributions are unknown.

The estimation of expression (A1) also involves the unobserved latent variable $U(e^*)$ (see equation (6) for details) related with observed discrete choices. Following Albert and Chib (1993), LeSage and Pace (2009) replaced the unobserved latent variable with the estimated latent parameter. The underlying idea is that once the latent $U(e^*)$ is recognized as an additional estimable set of parameters, then $P(C | U(e^*)) = P(C | U(e^*), e)$. $U(e^*)$, the continuous variable, has replaced the binary variable e . As a result of this equality, the joint posterior distribution of C can be regarded as a Bayesian regression problem with a continuous variable instead of a discrete one.

Following LeSage and Pace (2009), we compute the conditional distribution of the spatial lag model based on normal prior for β , uniform prior for the spatial parameter for ρ and truncated multivariate normal distribution prior to $U(e^*)$. Further, we also assume $\sigma_u^2 = 1$, which is required for identification. To approximate the posterior distribution (A1), we need to

sequentially sample from the following three conditional distributions: $P(\beta \mid \rho, U(e^*))$, $P(\rho \mid \beta, U(e^*))$ and $P(U(e^*) \mid \beta, \rho)$.⁸

We estimate these models for the 432 farmers of our sample, using software package Matlab. In our application, $\omega = \{e, X, W\}$. Specifically, $e = 1$ for 211 adopters of soil conservation and $e=0$ for 221 non-adopters of soil conservation (see Section 6.2 for details), X consists of a constant term and other explanatory variables, such as socioeconomics variables, market access variables, farm characteristics and information on soil conservation practice in the immediate upstream neighbourhood (see Section 6.3 and Online Appendix 2 for details), and $W =$ inverse distance decay or contiguity matrix (see Section 6.1 for details). $U(e^*)$ is the unobserved latent effort associated with the observed adoption or non-adoption of soil conservation measure. The spatial analysis is built on 1,000 MCMC draws and 100 passes. We separately conduct another run with 2000 MCMC draws and 200 passes, and find that both runs produce almost identical results.

⁸ See LeSage and Pace (2009) for detailed discussion of estimation method and conditional distributions.

Online Appendix 2: Description of Socioeconomic Characteristics, Market Access

Variables and Farm Characteristics

A2.1 Socioeconomic Characteristics

In the literature, the socioeconomic characteristics of households that have been found relevant for adoption of soil conservation practices include age of the household head, years of education of household head, proportion of members active in labour market in a household, household size and proportion of household members who have at least 10 years of schooling.⁹

The summary statistics for socioeconomic characteristics are presented in Table 2. The average age of the household head in our sample is 53. The average years of education of household head is only four years, with adopters having one more year of education than non-adopters. Adoption decisions may be made jointly by several household members (Teklewood et al., 2014 quoted from Zepeda and Castillo, 1997). Therefore, we include the proportion of household members who have at least 10 years of schooling as one of the explanatory variables; in our sample, approximately 22 percent of the household members of a family have studied more than 10 years.¹⁰

A2.2 Market Access

Since higher transaction costs deter farmers from adopting soil conservation practices, these are expected to negatively influence adoption (Teklewood, 2014). In our study, we measure transaction cost by considering market access and by using two variables: distance to the nearest all-weather road and local market as reported by the respondents. The summary statistics of these variables are presented in Table 2. The distance to the nearest local market and all-weather road is lower for adopters than for non-adopters.

A2.3 Farm Characteristics

We treat the total Farm area of the farmer as exogenous and as a household endowment, since most respondents reported that they inherited the land they were cultivating and did not purchase it.

Farmers' perceptions of the fertility and stoniness of the soil of their operational holdings are important determinants of the adoption of new technology; less fertile farms are more likely to

⁹ 10 years of schooling represents completion of high school education.

¹⁰ There are other household characteristics that affect adoption of soil conservation practices, like risk attitude (Shiveley, 2001), discount rate, (Stocking & Murnaghan, 2001), etc. We assume that risk is correlated with landholding size, but do not include it separately as an explanatory variable.

see adoption. Topographical features can also influence adoption: altitude, soil colour, soil texture and soil stoniness help capture this. Farmers who own farms that have better topographical characteristics may be less likely to adopt soil conservation technology (Teklewood et al., 2014). We asked the farmers to report their perception of these farm characteristics on a hedonic scale (see the footnote below Table 2). The total farm area of the adopters seems more than non-adopters. However, the altitude of the farm of non-adopters is more as compare to adopters.

We conduct a two-sample test of difference of these qualitative farm characteristics (Table 2). Adopters and non-adopters are statistically different in soil colour and soil stoniness. Adopters are reported to have more black soil and less stoniness on their farms. Both of these are considered better farm characteristics, so it would appear that adopters have soil that is more fertile.¹¹

Very high erosion prone sub-watershed Dummy ^{††}	-0.030 (0.107 to 0.52)	-0.013 (-0.055 to 0.027)	-0.043 (-0.161 to 0.80)
Sub-watershed treatment Dummy ^{†††}	-0.0134(-0.093 to 0.064)	-0.007 (-0.055 to 0.035)	-0.021 (-0.146 to 0.096)
Information on Soil Conservation Practice in Immediate Upstream Neighbourhood			
Contour Bunding (%)	0.168 (0.029 to 0.291)	0.079 (0.011 to 0.177)	0.248 (0.047 to 0.438)
Afforestation (%)	0.229 (0.118 to 0.347)	0.110 (0.026 to 0.220)	0.340 (0.170 to 0.525)
Bamboo Plantation (%)	0.158 (0.034 to 0.283)	0.077 (0.007 to 0.170)	0.236 (0.046 to 0.425)
Contour Bunding X Afforestation (%)	-0.004 (-0.043 to 0.045)	-0.002 (-0.025 to 0.021)	-0.006 (-0.067 to 0.063)
Contour Bunding X Bamboo Plantation (%)	0.065 (-0.039 to 0.187)	0.032 (-0.019 to 0.105)	0.98 (-0.058 to 0.282)
Afforestation X Bamboo Plantation (%)	-0.146 (-0.257 to -0.018)	-0.065 (-0.156 to -0.005)	-0.201 (-0.402 to -0.026)

Sources: 1) A primary survey carried out in Darjeeling District, West Bengal, India, in the year 2013, 2) Kalimpong Soil Conservation Division (2010), Kurseong Soil Conservation Division, (2011).

Notes: 1) Standard deviation in parentheses, 2) ***, ** and * indicate significance at 1, 5 and 10 percent respectively, 3) Adopter => farmers who adopted at least two soil conservation practices from stone bunding, afforestation and bamboo plantation; Non-adopter => farmers who adopted, at most, one soil conservation practice, 4) Number of adopters: 211, number of non-adopters:221, 5) In treated sub-watersheds, the state forest department of West Bengal has taken soil conservation measures. In untreated sub-watersheds, no government initiative for soil conservation, 6) \$ Sediment Yield Index is 1450 and above, \$\$ Sediment Yield Index 1350 -1449, \$\$\$ Sediment Yield Index 1250-1349, "Sediment Yield Index" calculated as "weighted arithmetic mean of the products of the erosion intensity weightage value and delivery ratio over the entire area of the hydrologic unit by using suitable empirical equation" (Soil and Land Use Survey of India, slusi.dacnet.nic.in/trs.pdf, February 2, 2014), 7) Soil texture, soil color and soil stoniness have been reported by the respondent according to a hedonic scale. Scale of soil texture: sandy/coarse--- 1, loamy/medium coarse—2, clay- 3, silt-4; Scale of soil color: grey - 1, reddish - 2, brown - 3, black – 4; Scale of soil stoniness: high stoniness- 1, medium stoniness- 2, low stoniness-scale 3, non-stony- 4. 8) Direct, indirect and total effect is based on equation (19).

Online Appendix Table 3: Spatial Lag Probit Model Estimates of Factors Influencing Adoption of Soil Conservation Practices with Neighbourhood up to Three Kilometres (alternative adoption definition)

Variable	Direct Effect	Indirect Effect	Total Effect
Socio Economic Variables			
Age of the Household Head (Years)	-0.001(-0.005 to 0.003)	-0.001(-0.008 to 0.003)	-0.002(-0.012 to 0.006)
Years of Education of Household Head (Years)	0.008(-0.004 to 0.020)	0.008(-0.005 to 0.031)	0.015(-0.010 to 0.046)
Household size	0.024(-0.001 to 0.052)	0.026(-0.001 to 0.093)	0.051(-0.002 to 0.135)
Household Member between age 14-65 (%)	-0.255(-0.480 to -0.045)	-0.282(-1.042 to -0.012)	-0.537(-1.442 to -0.083)
Proportion of household members studied at least 10 years	0.165(-0.061 to 0.386)	0.171(-0.058 to 0.712)	0.336(-0.111 to 0.991)
Experience of household head in agriculture (Years)	0.003(-0.001 to 0.008)	0.004(-0.001 to 0.013)	0.007(-0.001 to 0.018)
Market Access Variables			
Distance to Market From Farm (Meters)	-0.000 (-0.000 to 0.000)	-0.000(-0.000 to 0.000)	-0.000(-0.000 to 0.000)
Distance to all weather Road (Meters)	-0.000 (-0.000 to -0.000)	-0.000(-0.000 to -0.000)	-0.000(-0.000 to -0.000)
Farm Characteristics			
Farm Area (Acre)	0.018(-0.016 to 0.055)	0.017(-0.017 to 0.073)	0.035(-0.034 to 0.119)
Altitude of the farm (Meters)	-0.000(-0.000 to 0.000)	-0.000(-0.000 to 0.000)	-0.000(-0.000 to 0.000)
Soil Texture ^s	-0.031(-0.088 to 0.025)	-0.035(-0.158 to 0.021)	-0.066(-0.231 to 0.045)
Soil Colour ^{ss}	0.031(-0.017 to 0.077)	0.033(-0.016 to 0.137)	0.065(-0.032 to 0.200)
Soil Stoniness ^{sss}	-0.004(-0.065 to 0.052)	-0.001(-0.076 to 0.076)	-0.005(-0.130 to 0.122)
