# Chapter 5: Experimental Economics: An Introduction for Applications to International Trade

*Douglas D. Davis and Shannon K. Mitchell<sup>1</sup>*

## 5.1 Introduction

The use of laboratory methods to evaluate economic propositions has blossomed in the last two decades from being an isolated and curious novelty in the early 1970's to a widely accepted research method. At present, dozens of economic experiments are published each year, conducted in more than a score of experimental economics laboratories in the U.S. and around the world. Experimental methods have been used to investigate a wide variety of economic propositions in a diverse array of subfields. To the best of our knowledge, however, laboratory methods have not been used to investigate issues specific to problems in international trade. The absence of attention to trade issues is probably a consequence of the predominantly industrial organization and finance backgrounds of the early experimental economists.

Certainly, there is no inherent justification for this oversight. This paper is written as an introduction to experimental economics for trade theorists interested in considering laboratory techniques as an empirical method for evaluating trade issues. We proceed as follows. First, economics has traditionally been viewed as an inquiry not amenable to laboratory techniques. This perception remains among many economists, particularly in areas where experimental methods have not been used. For this reason, Section 5.2 is devoted to a discussion of our view of the methodological role of experimentation in economics. Section 5.3 describes how a simple market experiment is constructed and administered. Market experiments are by no means the only type of experiment useful in economic analysis and, in fact, some of the more obvious applications of experimental techniques to international trade issues involve the evaluation of predictions in noncooperative game theory. A market experiment is used for introduction because of the obvious nature of equilibrium predictions. Section 5.4 presents some guidelines for effective experimentation,

---

<sup>1</sup> We thank without implicating Ronald Harstad and Charles Holt for useful comments on an earlier version of the paper.

while Section 5.5 reviews some of the chief results of experimental inquiry. Possible applications of experimental techniques to issues in international trade are discussed in Section 5.6. Finally, some concluding remarks are offered in a brief section, 5.7

Prior to proceeding, we note that a healthy dose of skepticism is appropriate, and indeed useful. Although there are a number of empirical issues in virtually every area of economics that can be fruitfully addressed with laboratory methods, there are also a number of other empirical issues where experimental methods are *not* likely to offer particularly helpful insights. For example, little information is likely to be generated in the laboratory regarding the elasticity of imports and exports to tariffs. Even if we succeed in convincing the reader that experimental methods are a potentially useful means of collecting information relevant to some economic propositions, a critical eye toward what could be learned from any particular laboratory investigation can serve as an invaluable guide toward the fruitful application of this empirical method.

## 5.2 Experimental Analysis as an Empirical Technique<sup>2</sup>

### 5.2.1 Experimental Analysis and the Social Sciences

Almost universally, scientists construct theories to organize and explain behavior. The typical expectation is that these theories are grounded in empirical reality, in the sense that they are evaluated on the basis of their capacity to predict outcomes. For example, a chemical theory predicting the explosive volatility of fixed proportions of gypsum, charcoal and sulfur in the presence of heat could be tested by lighting a firecracker.

Notably, although actually generating and evaluating theories requires considerable cleverness, the *process* of theory evaluation is at once both methodologically straightforward and intuitive. As a first matter, one would like to know if there is any circumstance under which the theory works. By progressively controlling for auxiliary assumptions, the theory can be given a "best shot". Suppose, for example, that the firecracker does not explode. The failure immediately suggests a series of additional tests which control for auxiliary factors that may have prevented the predicted response. For

---

<sup>2</sup> A lengthier discussion of these issues that follows along the lines presented here appears in Chapter 1, Davis and Holt (1991).

example, was heat actually present? Perhaps the fuse did not burn all the way into the gunpowder. Again, other chemicals (such as water) might impede the process. Was the gunpowder wet? If the theory fails to work even under the most carefully controlled circumstances conceivable, then it tends to be rejected.<sup>3</sup>

On the other hand, if the predictions of a theory are confirmed in initial experimentation then investigation typically proceeds in the other direction, with a series of "stress tests" or boundary experiments, designed to examine the range of the theory's application. A junior high school chemist, for example, might want to know the sensitivity of the explosion to variations in the proportions and mix of the chemicals. Finally, in the course of evaluating a theory's range of application, persistent empirical regularities are often observed which are not part of the theory, but which suggest theory modification. For example, in the process of evaluating the limits of application for the above gunpowder theory, it may be observed that the rate of successful explosions varies inversely with the size of the firecracker encasement. For the junior high school chemist, this might represent an anomaly to be explored in its own right. Perhaps it will lead to a refinement of the young chemist's theory, e.g., the gunpowder theory might ultimately be modified to suggest that oxygen is also critical to an explosive chemical reaction. This process of identifying a baseline, exploring the limits of application for a theory, and noting empirical regularities in controlled conditions lies at the very heart of theory development, evaluation, and refinement in the physical sciences.

Although economics shares with the physical sciences the property of a rich and elegant theoretic structure, economic theory has been developed, refined, and evaluated in a different manner, almost exclusively outside the laboratory. A traditional position among economists is that laboratory methods are not applicable to economics due to the subject and scope of economic study: humans interacting in social institutions. Unlike physical processes, it is argued, economic events occur in circumstances so complex as to be spatially and temporally unique. By this reasoning, assumptions auxiliary to economic theories cannot be progressively controlled, and the only way to evaluate economic propositions is through the application of statistical techniques to data from the natural world. Experimental economists contest the distinction of economics from the physical

---

<sup>3</sup> There rarely (if ever) exists an ultimate rejection of a theory. Rather, scientists tend to give up on one theory when it fails to work in any environment of practical concern.

sciences, arguing that the difference is one of degree, rather than kind. While it is quixotic to attempt to evaluate an economic theory in a laboratory context that retains the richness of the parallel natural context, it is often possible to construct a very sparse laboratory environment that meets the stated assumptions of a particular theory. If the theory fails to organize data in the simple laboratory environment, then it cannot be expected to motivate behavior in the more complicated natural world.<sup>4</sup>

Notably, the comparative sparseness of the economics experiment limits the kinds of conclusions that can be drawn from experimental investigation. In many standard applications in the physical sciences, the distinction between observation in the laboratory and in natural contexts is often minor. We would, for instance, expect the laboratory conditions for the gunpowder experiment to be substantially the same as conditions outside the lab. Therefore, we would expect the results of investigations into the limits of the "gunpowder theory" to have direct relevance to the natural world. Economists, however, must generally be more circumspect in making claims about behavior in the natural world. For example, the predictions of static Nash equilibrium theory could be tested in the laboratory by presenting a pair of participants with a simple prisoners' dilemma game in normal form, and offering them the opportunity to make simultaneous choices to earn the monetary amounts listed in the game's representation as the outcome of their actions. Even a laboratory result most supportive of the Nash equilibrium prediction would allow little to be said about performance in the natural world. One would generally not expect to see agents facing anything even vaguely resembling the normal-form game structure in any natural application of a prisoners' dilemma. Moreover, extenuating circumstances in the natural context would undoubtedly invite debate as to whether the agents actually faced the dilemma.

While the increased distance between the laboratory and the natural world limits the claims that can be made about the natural world from economics experiments, it does not impair the usefulness of experimentation in economics. To repeat: If the theory fails to organize behavior in very simple environments, it generally cannot be

---

<sup>4</sup> At a minimum it is incumbent upon the theory's remaining proponents to indicate the manner in which it is presumed to apply to complex environments when it fails in simple environments.

expected to organize behavior in the more complicated natural world. It is principally (but by no means exclusively) this role of evaluating theory that experimental techniques are useful in economics.

### **5.2.2 The Value of Experiments in Economics**

The value of experimental techniques is highlighted by considering the difficulty of testing many economic propositions with data from the natural world. A surprising variety of very basic economic propositions is difficult or impossible to evaluate with naturally occurring data. Consider, for example, the competitive markets hypothesis fundamental to any economics principles course: Given sufficient information and barring market power, the price and the quantity of a traded private good is determined by the intersection of market supply and market demand curves. Both practical and inherent data constraints impede the identification of market supply and demand curves in natural markets. Competitive concerns often provide incentives for firms to disguise cost information. Moreover, firms are generally not interested in the same data as economists, and (as would be attested by anyone who has ever attempted to calculate a firm's costs for a predatory pricing investigation) relevant cost information is often simply not collected. Even more fundamental data problems exist on the demand side. Consumers make decisions on the basis of perceived utility, which is impossible to observe directly.

Sophisticated statistical and econometric techniques have enabled researchers to make remarkable claims from limited available data in natural markets. These techniques, however, necessarily rely on yet other assumptions which are not directly observable in natural markets. Simultaneous equations methods, for example, may be used with transactions price data to circumvent the above-mentioned problems associated with obtaining natural cost and utility information to estimate market supply and demand relationships. But, even transactions prices are difficult to observe, particularly in markets where sellers discount to gain strategic advantage. Moreover, simultaneous equations techniques typically presume that markets equilibrate. Using this method, demand is estimated as a collection of equilibrium points determined by a series of supply shifts; conversely for supply. It would, of course, be circular to subsequently use the estimated supply and demand curves to evaluate the proposition that

markets equilibrate.<sup>5</sup>

Data collection and availability problems of this type are pervasive in economics. The inability to test even basic propositions has led theorists to evaluate models on the basis of factors other than predictability, such as internal consistency and elegance. For this reason, wide classes of economic models are constructed without systematic thought to verifiability. The careful use of laboratory methods can help provide an empirical basis for refining, discriminating among, and perhaps rejecting some of these economic theories.

### 5.3 A Simple Market Experiment

It is instructive to consider how a researcher interested in evaluating the predictions of competitive price theory might construct a simple laboratory market.<sup>6</sup> Suppose the researcher enters a classroom full of volunteer participants, and passes out a number of cards, which are either green or yellow. On each card a number appears, denominated in dollars and cents. The green cards are seller cards, and the printed number represents the cardholder's sales cost for selling a "unit". A participant holding a seller card could earn as profits the difference between a negotiated unit sales price and the selling cost. Thus, the individual cost figure represents a lower bound on acceptable sales prices for the card holder. A market supply schedule is induced by providing each seller with different sales costs. Arraying costs from lowest to highest generates a supply curve, as shown as the bolded line on the left side of **Figure 5.1**. For example, the step on the lower left part of the supply curve results from giving a seller a unit with a cost of \$3.75 and the subsequent step results from giving a second seller a unit with a cost of \$3.95.

Demand may be symmetrically induced with the yellow buyer cards. The number printed on each buyer card represents a redemption value. An agreement to pay a buyer the difference

---

<sup>5</sup> There is a literature that attempts to estimate supply and demand functions with disequilibrium data (see e.g., Ito, 1981). It is doubtful that these models importantly mitigate the problems discussed in the text, as they typically rely on specific, ad hoc assumptions about a particular price convergence path.

<sup>6</sup> This method of supply and demand inducement very closely resembles that used in the first market experiments. See, e.g., Chamberlin (1948), and Smith (1962, 1964, 1965).

**Figure 5.1.**  
**Induced Supply and Demand Arrays, and the Sequence of**  
**Contracts for a Double Auction Experiment.**

(Source: Session Iipda 24; Smith and Williams, 1983.)

between the printed redemption value and a negotiated sales price implies that the printed value represents a maximum willingness to pay. Varying the unit valuation steps and arraying units from highest to lowest valuation generates a demand schedule, such as that shown on the left side of Figure 5.1. For example, the highest step in the upper left corner of Figure 5.1 is the result of giving a buyer a unit value of \$5.55, and the subsequent lower step is the rule of giving a second buyer a unit value of \$5.35. Notice that construction of supply and demand allows clear *a priori* identification of competitive price and quantity predictions. In this case the competitive price prediction is \$4.70 and the competitive quantity prediction is either 6 or 7 units.<sup>7</sup>

<sup>7</sup> Due to the discrete number of exchangeable units, competitive predictions are characterized by some indeterminacy in either price or quantity. Early experiments were typically constructed with a unique price prediction, and some quantity indeterminacy as shown in Figure 5.1. In this sort of design, sales of the marginally profitable units may be induced via the payment of a small, but nonnegotiable per unit sales commission (e.g., in the Figure 5.1 session, buyers and sellers each received \$.05 per trade). Sales commissions are generally viewed today as somewhat undesirable, as they essentially shift the demand curve up and the supply curve down by the amount of the commission, creating a "price tunnel" where final trades can only be struck at a unique price. Most current designs are instead characterized by a vertical overlap, admitting some price ambiguity but predicting a unique quantity.

The process of trading units requires construction of a *market institution*, or a set of trading rules. A variety of alternatives exist. Consider, for example *double auction* or "stock-market" rules. At the beginning of a trading period of some specified duration, any seller may call out a price offer to sell, which is publicly written on a chalkboard at the front of the room. At the same time, any buyer may call out a bid to purchase a unit, which is also displayed on the chalkboard. (To avoid chaos, buyers and sellers are usually required to raise their hands and be recognized before calling out price offers or bids.) At any time a seller is free to make a sale at the price suggested by a buyer, or to post a new sales price. Buyers are free to accept any seller's offer price or to submit a new bid. Each time either a buyer or seller accepts the displayed terms of exchange, a transaction is executed and written on the board, the buyer and seller hand in their cards, and they record their earnings. Trade resumes as other buyers and sellers propose new terms of trade for remaining units, and continues until the expiration of the time period.<sup>8</sup>

Trades struck under these conditions in a representative trading period are illustrated as dots between the double line and the first vertical line to the right of the double line in **Figure 5.1**. Each dot is a transaction, represented in temporal sequence. There are 6 dots, so the quantity is 6, as summarized at the bottom of the figure. The process may be repeated by again passing out the green and yellow buyer and seller cards, and starting a new fixed-duration trading period. The temporal sequence of contracts for six additional trading periods are summarized by the information presented between the last 7 vertical bars shown on the right side of **Figure 5.1**.

As evidenced by the summary information displayed in the bottom three rows of **Figure 5.1**, the drawing power of competitive price and quantity predictions is striking. The price information presented in the bottom row reveals that the mean contract price is within \$.04 of the competitive prediction in all but one period (trading period 2). This occurred despite the fact that participants had no previous experience with the trading institution in this session. Similarly, inspection of quantity information in the second row at the bottom of the figure indicates that transacted quantities were within the competitive range in each trading period. Finally, consider the efficiency information summarized in the top row at the bottom of

---

<sup>8</sup> Double auction variants differ in the kind of bids and offers that are allowable, as well as in the way the sequence of bids and offers are stored. These rule variations have some effect on performance. For a discussion, see Davis and Holt (1991), Chapter 3.

**Figure 5.1.** In addition to price and quantity predictions, neoclassical price theory suggests that competitive markets are efficient in the sense that they maximize the possible gains from trade. Efficiency is typically measured in experimental markets as a surplus extraction rate, "E", which is the proportion of the realized gains from trade to the maximum possible gains from exchange under the competitive prediction. E is bounded between 0 and the competitive prediction of 100 percent. As with competitive price and quantity predictions, market efficiency extraction rates are very near the competitive prediction, at nearly 100 percent in every period.

#### 5.4 Some Guidelines for Effective Experimentation<sup>9</sup>

*Replicability* and *control* are the principal advantages of experimentation. Replicability refers to the capacity to independently verify results with new data.<sup>10</sup> Opportunities for unilateral verification enhance the credibility of data collection, providing both a "carrot" of accolades for the generation of new data, as well as a "stick" of professional embarrassment if others are unable to duplicate ones' findings.<sup>11</sup> Control is the capacity to refine the environment so as to eliminate auxiliary behavioral motivations. By controlling participant incentives and information flows, a laboratory market vastly reduces the number of auxiliary assumptions needed to evaluate a hypothesis.

The structure of an experimental investigation is key to fully exploiting the advantages of replicability and control. This section offers a series of five criteria that may assist in constructing a useful experimental test: *procedural regularity*, *motivation*, *unbiasedness*, *calibration*, and *parallelism*. These guidelines should not be construed as a laundry list of conditions to be satisfied before an experiment can

---

<sup>9</sup> For an expanded discussion of these guidelines, see Chapter 1, Davis and Holt (1991).

<sup>10</sup> Replication in an experimental context should be distinguished from the concept of replication in econometrics. In econometrics, replication refers to the capacity to reproduce one's results with a given data set. As Roth (1990) notes, in an experimental context replication is the capacity to create an entirely new set of observations.

<sup>11</sup> The desirability of placing professional credibility on data collection is not restricted to data collected in the laboratory. Much better data would also be generated from natural markets if it were collected by economists (rather than businessmen or bureaucrats) who had a professional stake in the data collection process.

be viewed as valid. While some characteristics (such as unbiasedness and calibration) may be fully satisfied *ex ante*, other features (such as motivation or parallelism) must be addressed, but cannot be fully verified. The satisfaction of these latter criteria is frequently the focus of debate over the generality and relevance of an otherwise well-constructed and executed experiment. Consider these terms, in sequence.

#### 5.4.1 Procedural Regularity

Standardization of procedures is critical for replication; thus, the guiding principle for standardizing and reporting instructions and procedures should be to permit a replication that both the researcher and outside observers would accept as being valid. The scope of standardization necessary for valid replication is wide. In addition to the text of instructions, the experimenter should report illustrative examples used, tests of subjects' understanding, the protocol for answering subjects' questions (e.g., no information beyond instructions), the nature of monetary or other rewards and the presence of "trial" or practice periods with no rewards. Procedural standards that should be adopted and reported include information regarding the subject pool, the method of recruiting subjects, the number and experience levels of subjects, procedures for matching subjects and roles, the location and typical duration of experimental sessions, any intentional deception of subjects, and any procedural irregularities in specific sessions that may require special interpretation. Journal space limitations all too often preclude the publication of many of these aspects, but they should be made available to journal referees and to interested readers upon publication.

#### 5.4.2 Motivation

Even under the most tightly controlled laboratory circumstances, the motivation for individual action cannot be directly observed, and motives for action in the laboratory may be diverse. In addition to "doing well" by maximizing otherwise meaningless points or hypothetical dollars in a laboratory experiment, participants may be motivated by boredom, an eagerness to satisfy the perceived objective of the researcher, or a desire to minimize the time spent in the laboratory. To enhance the likelihood that participants are motivated

in accordance with the incentives that are the subject of investigation, participants are usually paid monetary rewards related to outcomes. Critically, the rewards must be salient, in the sense that rewards vary both directly and prominently with the reward medium specified in the laboratory. There is little reason to expect payments to affect decisions if notably identical earnings are realized despite the decisions made.

This is not to say that all non-salient payments are undesirable. It is standard to pay participants an up-front appearance fee (perhaps \$3.00) in addition to the salient rewards. This fee has the administrative advantages that it induces prompt arrival and provides participants some incentive to pay attention to instructions. An up-front participation fee can also help to assure participants that there are no tricks; e.g., they will be paid cash as promised.

Determination of an adequate level of financial motivation is unfortunately somewhat elusive. Clearly there are diminishing benefits to increasing payment levels. Although behavioral variability tends to diminish with increases in salient financial incentives, the change in behavior is not always strictly monotonic. Individuals are bound by constraints of cognition, and in some instances, of social convention. Simply increasing financial incentives may not generate predicted responses. Just as the lure of \$6 million dollars could not induce either of these authors to dunk a basketball (despite our best efforts), increased rewards in the laboratory will not enable participants to perform tasks beyond their cognitive skill level. As a general practice, laboratory earnings for optimizing decisions are set so as to exceed slightly the opportunity cost of the participants' time in the laboratory.

### 5.4.3 Unbiasedness

The drawbacks of explicitly suggesting responses to experiment participants are clear, and incentives to replicate unusual laboratory results should temper the creation of intentionally deceptive research. Rather, this section is written to highlight the ease of introducing unintended bias, through inadvertent behavioral references (such as "collusion" or "conspiracy") and through verbal emphasis on certain terms. The laboratory researcher must be careful to not inadvertently suggest particular types of behavior. Careful attention to wording in experimental instructions can mitigate the effects of possibly pejorative language. The use of computers to present instructions can facilitate control over "experimenter" effects in both the reading of instructions and in the administration of laboratory sessions.

An interesting issue regarding bias and instructions has to do with the amount of context-related language to use in instructions, for there is a clear tradeoff. For example, in evaluating oligopoly market performance, obvious potential biases are presented by mentioning "cartels," "collusion" or "defections". On the other hand, the task of explaining the structure of the market to the participant is greatly facilitated by using market-specific references to "buyers", "sellers", and "contracts". To fully appreciate the benefit of these latter terms, consider for a moment the problem of explaining to participants the workings of the double auction described in Section 5.3 without any reference to buyers, sellers, unit costs, unit valuations, purchases or sales. Just what are participants doing if they are not buying and selling units of a commodity?

Unfortunately, no hard and fast distinction between elucidatory and pejorative language exists. As an alternative, we recommend starting the construction of any new experiment with standard instructions from published sources. Experienced and reputable experimenters have carefully considered sources of unintended bias in the creation of their instructions, and by their example may help a new investigator avoid troubling instruction effects.

#### 5.4.4 Calibration

Consider the sample market experiment discussed in Section 5.3, and illustrated in **Figure 5.1**. Although observed price, quantity and efficiency extraction rates appear to conform quite nicely to competitive predictions in **Figure 5.1**, it would be rather difficult to decide just what sort of alternative pricing performances would also be "close enough" to warrant a conclusion that a market was competitive. In fact, from a statistical perspective we cannot conclude that even the very stable price series observed in **Figure 5.1** conforms to competitive predictions. Rather, statistical inquiry is a process of falsification. With only the competitive hypothesis as a standard we would, at best, be unable to reject the hypothesis that the market illustrated in **Figure 5.1** generated competitive predictions.

Much stronger statistical support for a hypothesis can be generated through the process of rejecting rival predictions. For example, the monopoly prediction may represent a natural alternative to the competitive markets hypothesis. As can be seen by the marginal revenue curve (MR) in **Figure 5.1**, the optimal price and quantity choices for a monopolist (or cartel) are \$5.15 and 3 units, respectively.

Sufficient replication of markets conducted in the **Figure 5.1** design with different groups of participants might allow rejection of the cartelization hypothesis. This is the practical problem of calibration. Theories are much more meaningfully evaluated in light of alternatives. Rejection of alternative behavioral motivations strengthens a failure to reject the maintained hypothesis.

Behavioral "noise" is inevitable. The residual price variability in the final periods of the market shown in **Figure 5.1**, for example, is a general characteristic of the robustly competitive double auction. In light of this behavioral noise, we offer two additional comments on the issue of calibration. The first is a design issue. Careful experimental design requires more than merely identifying rival predictions. The behavioral consequences of rival predictions should further be sufficiently distinct to be readily differentiated in observations from inherent performance variability. It would be very difficult to distinguish cartelized from competitive pricing performance in the market experiment illustrated in **Figure 5.1**, for example, if the demand curve was so elastic that the price difference separating the predictions was only \$.05.

The second issue has to do with anticipated performance variability that is outside the domain of the theory. Although some behavioral variability is effectively irreducible noise, there exist other theoretically irrelevant factors that quite regularly affect performance, such as experience with the experimental environment, group effects, and the order in which treatments are presented. In order to draw legitimate statistical claims regarding performance, it is important to control for these anticipated sources of variability. This can be done with the careful use of block designs, or by systematically rotating treatments across expected sources of variability. For example, the market shown in **Figure 5.1** used 4 sellers and 4 buyers. Suppose we were interested in evaluating the effects on performance of reducing the number of sellers to one. A variety of predictable but theoretically irrelevant sources of variability might affect observed behavior. Some groups, for instance, may simply be more competitive than others. The effects of either particularly rivalistic or particularly cooperative groups may be controlled by conducting both the 4 and 1 seller treatments in a single session. Similarly, monopolists may price more (or less) aggressively after having experience in a competitive market. Alternating the order of the treatments could control for sequence effects of this sort. There could also be individual effects. Independent of a treatment sequence effect, some individuals may be more intent on manipulating prices favorably than others, particularly as monopolists. If it is not reasonable to construct a design where each

seller holds the monopoly position, then the method of selecting the monopolist must be replicable, and for most purposes should be neutral (determined, for example, by the roll of a die).

#### 5.4.5 Parallelism

Not all experiments are (or need to be) constructed to test formal theory. Useful insights into the possible performance consequences of newly-created trading institutions have been generated via laboratory experimentation. Examples include the construction of auctions to allocate slots for commercial and scientific projects on the NASA space station (e.g., Banks, Ledyard and Porter, 1987), and auctions for transportation rights to natural gas pipelines (McCabe, Rassenti and Smith, 1988; Plott, 1988). In both cases, demand for one good is dependent on the price and availability of related goods: demand for transportation rights over a given pipeline segment is sensitive to the availability of transportation links connecting the segment to the wellhead and to the consumer. Similarly, demand for a physical spot on a space station is dependent upon the availability of astronauts to service and monitor the installed hardware and other characteristics, such as exposure of the physical spot to the sun. Simply identifying a set of reasonable equilibria in complex environments of this type often strains the modelling tools of the skilled theorist. Theory, moreover, can often provide little insight into either the dynamic performance of such markets, or to the behavioral appeal of competing equilibria. A laboratory experiment incorporating features parallel to the relevant problem in a natural market can offer some insight regarding these issues of dynamic performance and equilibrium selection.

The usefulness of even well-constructed experiments of this sort lies in the inclusion of parallel elements perceived as critical to the natural context under consideration. As with the issue of subject motivation, parallelism is an issue that cannot be indisputably satisfied. Rather, debate over the applicability of the study will rest on the success with which the relevant problem is believed to have been induced in the laboratory.<sup>12</sup>

A final issue in parallelism regards subject selection. College

---

<sup>12</sup> Plott has likely done more experimental investigations with public policy implications than anyone, and does a commendable job addressing this issue of parallelism. See in particular Plott (1987).

undergraduates are typically chosen as participants, due to availability and to the low opportunity cost of their time. Of course, these participants may lack relevant sophistication, and may know less about the natural context than the actual agents involved. As a general matter, however, we do not deem it necessary to use participants from the natural parallel circumstance. The costs of conducting experiments with such "relevant" professionals can often be quite high, due to the high opportunity cost of their time. Moreover, a variety of experiments reporting alternative treatments using undergraduates and relevant professionals as participants suggest that the added benefits of using the relevant professionals may be minimal. Generally, the shift in subject pools had no significant behavioral consequence (see, for example, DeJong, Forsythe, Lundholm, and Uecker, 1985; Mestelman and Feeny, 1988; and Smith, Suchanek and Williams, 1988).<sup>13</sup> Given a sufficiently simple design and sufficiently motivated participants, the behavioral aspects theory can be given a reasonable test even without participants from the natural context.

Subject sophistication nonetheless warrants consideration. There are a number of studies that indicate that performance varies with proxies for the aptitude of participants, such as the undergraduate institution (e.g., Davis and Holt, 1990) or using graduate instead of undergraduate students (Kagel, Levin and Harstad, 1988). In some instances choosing a specific participant pool may be appropriate. If such a choice is made, then that should be explicitly reported, along with a rationale for the choice.

## 5.5 Some Central Results of Economic Experimentation

The experimental literature within industrial organization alone is extensive, and any attempt to categorize results would clearly exceed the scope of this paper. A number of excellent surveys of experimental findings are available.<sup>14</sup> Rather than attempt to present a

---

<sup>13</sup> Some differences between behavior of the undergraduates and relevant professionals in the laboratory suggests that undergraduates may actually represent a preferred subject pool in some instances. Businessmen involved in natural markets parallel to a market under investigation sometimes attempt to apply rule-of-thumb guidelines that are useful in the more complicated natural market, but are useless in the streamlined laboratory implementation. See, e.g., Burns (1985) and Dwyer, Kagel and Levin (1989).

<sup>14</sup> See Plott (1982, 1989), Roth (1988) and Smith (1982).

compendium of results, this section briefly discusses the origins and results of two types of economic experiments, market experiments and game theory experiments.<sup>15</sup> We illustrate these conclusions by showing the results of sample laboratory sessions to give the reader some feel for designs and the data generated in the laboratory. The discussion is divided into three parts. In subsection 5.5.1, we discuss principle results and applications of market experiments. Subsection 5.5.2 reviews the origins and some central findings of experimental examinations of the predictions of noncooperative game theory. A brief summary is offered in the subsection 5.5.3.

### 5.5.1 Market Experiments

The experimental investigation of markets was initiated by Chamberlin (1948) who believed that aspects of the Great Depression could be explained by certain deficiencies in neoclassical price theory. Frustrated by the absence of relevant data from the natural world, Chamberlin induced costs and values in a classroom market in a fashion very similar to that explained in Section 5.3 (see **Figure 5.1**). Unlike the market discussed above, however, Chamberlin allowed participants to mill about the classroom and privately negotiate contracts.

Chamberlin's markets did not generally achieve competitive outcomes. In particular, the quantity exchanged persistently exceeded the competitive prediction. Smith, who observed the experiments as a graduate student, thought that the privacy of communications in Chamberlin's "negotiated price" trading rules failed to give competitive price theory a "best shot", and structured an alternative experiment under the double auction rules described above. Smith's (1962, 1964, 1965) support for competitive price theory generated little more initial interest from the profession at large than Chamberlin's rejections. But Smith became intrigued by the effect of trading rule manipulations on market outcomes and initiated a stream of experimental research into the performance of markets. The robustness of competitive price predictions and the sensitivity of markets to alterations in the trading

---

<sup>15</sup> We ignore a third type of economic experiments, e.g. individual decision-making experiments. These experiments grew from efforts to evaluate the credibility and consistency of assumptions in Savage/von-Neuman Morgenstern expected utility theory, and this literature has generated a number of very provocative findings. (See, e.g., Thaler, 1987.) While instructive, these experiments seem less applicable to international trade issues.

rules defining the institution of exchange represent perhaps the central themes of this stream of research. We elaborate upon these broad conclusions below.

*Competitive predictions generally tend to organize experimental market data very well -- particularly those organized under double auction trading rules.* As mentioned above, the tight adherence of the contracts to the competitive price and quantity predictions shown on the left side of **Figure 5.1** is characteristic of a wide body of experimental markets. To illustrate this point, it is instructive to review results of two double auction market sessions reported in studies designed to assess the boundaries or limits of application for competitive price predictions for double auction markets. The dimensions considered are: (a) the distribution of producers' and consumers' surpluses and (b) the number of sellers necessary to reliably generate competitive predictions as outcomes.

Consider first the question of the range of surplus distributions between buyers and sellers that will behaviorally generate competitive price and quantity outcomes. This boundary may be tested in a market where a number of sellers all have common and constant costs, and where a number of buyers all share constant and common unit values. By varying the aggregate numbers of units available to buyers vis-a-vis sellers, the entire surplus will go either to buyers or to sellers in the competitive prediction. This situation is illustrated in the supply and demand arrays shown in **Figure 5.2**. This market is composed of 4 sellers and 4 buyers. Equilibrium E1 is characterized by excess demand: demand curve D1 is characterized by 16 units at a constant unit value of \$6.80 per unit, while supply curve S1 is composed of 11 units at a constant unit cost of \$5.70 per unit. Given the excess demand and the unit cost valuation, all the surplus goes to sellers at a competitive price of \$6.80. The surplus distribution condition is reversed by creating excess supply in equilibrium E2. In E2 demand is reduced to 11 units and supply is increased to 16 units.

The results of an oral double auction market conducted in this design reported by Holt, Langen and Villamil (1986) is illustrated by the sequence of contracts shown on the right side of **Figure 5.2**. In the first five 5-minute trading periods, supply and demand conditions S1 and D1 were in effect. After period 5, some sellers were given an extra unit, and units were taken away from some buyers in an unannounced shift to supply and demand conditions S2 and D2. Trade resumed under these conditions for an additional five 5-minute periods. As suggested by the sequence of contracts, the drawing power of competitive predictions are robust to extreme surplus distribution predictions. Competitive outcomes are generated even when one side

**Figure 5.2.**  
**A Double Auction Market Session Conducted Under**  
**Severe Earnings Inequities**  
 (Source: Holt, Langen and Villamil, 1986).

of the market receives none of the available surplus. The results of this session are representative of other experiments in similar designs by Smith (1965), Smith (1980) and Smith and Williams (1989).

As a second boundary issue, consider the minimum number of sellers necessary to ensure a competitive price/quantity outcome. **Figure 5.3** illustrates the results of a monopoly double-auction session reported by Smith (1981). Notice from the sequence of contracts in the figure that the monopolist was singularly unsuccessful in raising the price to the monopoly prediction of 110. In fact, prices in later periods were below the competitive prediction of 80. Some double auction monopolists fare better than the seller shown in **Figure 5.3**. Many, however, do not. Markets with two sellers generate competitive predictions even more regularly, and some commentators (e.g., Smith and Williams, 1989) suggest that double-auction markets with as few as three sellers are robustly competitive. In any event, a large number of sellers are unnecessary to ensure competitive outcomes.

Competitive predictions have been robust to a variety of other boundary examinations, including between-period shifts in market

**Figure 5.3.**  
**A Double Auction Monopoly.**  
 (Source: Smith, 1981)

supply and demand arrays (Williams, 1979; Williams and Smith, 1983; Davis, Harrison and Williams, 1991), multiple commodities (Williams, Smith and Ledyard, 1985) and even explicit conspiracy (Isaac and Plott, 1981). Competitive predictions appear to break down in double auctions only occasionally, and only under very extreme circumstances, such as completely random supply and/or demand shocks, markets characterized by a single seller, and markets characterized by market power, where each of a number of sellers can unilaterally increase prices (Holt, Langen and Villamil, 1986, Davis and Williams, 1991).

*The trading rules defining the institution of exchange matters a great deal.* Markets may well be organized under institutional trading rules other than the double auction, and these alternative structures can affect market performance substantially. Consider, for example, the effects of shifting from double auction trading rules to a posted offer institution (as typifies retail sales). The predominant characteristic of posted-offer markets is that sellers publicly submit binding price offers that remain in effect for some period of time.

The standard laboratory implementation of the posted offer proceeds as a series of 2-step trading periods (see, for example, Ketcham, Smith and Williams, 1984). Within each period, sellers first

privately and simultaneously select price and maximum quantity offers. Prices (but not quantities) are then publicly displayed to the market. The second step is a shopping sequence, where buyers are drawn one at a time from a waiting mode to make purchases. Each buyer may make as many purchases as desired from sellers' inventories on a take-it-or-leave-it basis, at the posted prices. The period ends when all buyers have shopped, or when all sellers are out of units.

Markets organized under posted-offer trading rules are behaviorally similar to double auction markets in many respects. In particular, posted-offer markets tend to competitive outcomes in a wide variety of circumstances. Posted-offer markets, however, tend to the competitive equilibrium price from above, and they converge more slowly than comparable double auction markets. Moreover, the range of application for competitive predictions is much more limited in posted-offer markets than in double auctions, and it is possible to design posted offer markets characterized by monopoly or market power which consistently and dramatically deviate from the competitive price. Consider, for example, the sequence of contracts for the posted-offer monopoly market shown in **Figure 5.4**. This market, reported by Smith (1981), was conducted under the same supply and demand conditions used in **Figure 5.3**. In stark contrast to the double auction monopoly illustrated in **Figure 5.3**, the posted-offer monopolist achieved both high and stable prices at the monopoly level at the end of the session.

We would be remiss if we did not hasten to add that not all posted-offer monopolists are as successful at extracting the monopoly price prediction as the monopolist shown in **Figure 5.4**. **Figure 5.4** is representative, however, in the sense that posted-offer monopolists generally extract supra-competitive prices (e.g., Isaac, Ramey and Williams, 1984). Posted-offer markets have also been shown to be susceptible to explicit conspiracy (Isaac, Ramey and Williams, 1984), tacit conspiracy in duopolies of long duration (Stoeker, 1980; Alger, 1987; and Bensen and Faminow, 1988; ) and market power (Davis, Holt and Villamil, 1990; Davis and Williams, 1991). Markets organized under posted-offer trading rules also respond poorly to unannounced between-period shifts in market supply and particularly market demand curves (Davis, Harrison and Williams, 1991).

This "posted-offer effect" has important policy implications. For example, as an experiment by Hong and Plott (1982) suggests, barge operators on the Mississippi had good reason to be skeptical of proposals (by the railroads) to limit barge freight-rate negotiations and require public, binding price postings. In a laboratory setting that

**Figure 5.4.**  
**A Posted Offer Monopoly.**  
 (Source: Smith, 1981)

paralleled the demand, cost and concentration characteristics of the market for barge transportation services on the Mississippi river, Hong and Plott found that public price posting tended to generate higher prices, making alternative transportation services, such as the railroads more competitive. Plott (1986) similarly reports that concerns about the effects of binding public price postings discouraged the Civil Aeronautics Board from imposing "posting rules" in a market for airline landing slots. There are many other examples. Rather than highlight the effects of this particular trading rule manipulation, however, our purpose is to document the importance of trading rule adjustments on market performance in general. The effects of institutional or trading rule adjustments on performance stands as one of the most prominent results of experimental inquiry. Manipulations in the structure of voluntary contributions mechanisms for public goods provision, for example, have been shown to alter public goods provision levels dramatically (e.g., Isaac and Walker, 1988), and changes in the structure of one-sided auctions (e.g., auctions for Treasury bills and artwork) importantly affect both the revenue and efficiency characteristics (e.g., Cox, Roberson and Smith, 1982).

In summary, the examination of market behavior in the laboratory is largely a study of the effects of institutional adjustments on market performance. The extreme resiliency of competitive predictions in markets organized under the double auction trading institution has led to use of double auction markets as the behavioral standard against which performance of rival institutions is evaluated. Double-auction trading rules are interesting in their own right, due to parallels of double auction rules to attributes of many modern financial markets. Deviations from double auction rules can importantly affect market performance. In particular, competitive predictions are invariably generated in a narrower range of circumstances in markets organized under a posted-offer trading institution.

### 5.5.2 Tests of Noncooperative Game Theory

For ease in presentation, most of the discussion to this point has been in terms of market experiments. A very large body of economics experiments, however, have been conducted to evaluate the predictions of noncooperative game theory. Experimental tests of game theory originated with psychologists, sociologists and political scientists who were skeptical that individuals would jointly reason themselves to Pareto-inferior outcomes in a prisoners' dilemma context. The relationship of simple generalizations of the prisoners' dilemma game to problems of oligopoly cooperation sparked interest among economists desiring to evaluate the predictions of Cournot and Bertrand models of noncooperative behavior (e.g., Fouraker and Seigel, 1963; Murphy, 1966; and Dolbear *et al.*, 1968). These experimental investigations focused on behavioral issues under conditions that more nearly matched the conditions of noncooperative game theory. For this reason, elements of natural markets (such as pricing rules, and buyer decisions) were subsumed and participants were presented with more information than is usually made available in a market experiment regarding, for example, information about demand as well as the costs of other sellers. Thus these investigations are even closer to pure-theory tests than market experiments, and the value of such experiments lies, in large part, in the relationship between the environment created in the laboratory and the relevant theory.

There has been a resurgence of interest in experiments testing equilibrium predictions of noncooperative game theory lately, with much of the current focus on the behavioral properties of Nash equilibrium refinements, the resolution of coordination problems, and on noncooperative bargaining theory. Again, although it is well beyond

H. As is readily apparent from inspection of the panels in **Figure 5.5**, both equilibria involve "pooling" in the sense that player 2 will not be able to discriminate among L and H type player 1's on the basis of the signal player 1 sends with the decision to play A or B.

Consider equilibrium E1, shown in the left panel of **Figure 5.5**. In E1 player 1 selects action B, regardless of type, and player 2 responds by picking C. It can be verified that this is a sequential equilibrium by considering the gain to a unilateral deviation by either player. For player 2, action C is an equilibrium response because it is more likely that a player is of type H than type L, making the 125 payoff more likely than the payoff of 75. Verifying the optimality of action B for player 1 involves a more subtle calculation, as it depends on player 2's response to a deviation by player 1, which in turn depends on the assumption player 2 makes about the player 1 type most likely to deviate. In equilibrium E1, player 2 assumes that type L player 1's are more likely to select action A. Player 2's assumption about who deviates, as well that player's best response (action D), is illustrated by the dashed line. Player 1 will find deviation from action B unprofitable, regardless of type. Hence E1 is an equilibrium.

By similar reasoning, equilibrium E2, shown on the right side of **Figure 5.5**, is also a sequential equilibrium; action C maximizes player 2's expected income, given both H and L type players select action A. These outcomes are highlighted by the bolded lines. As indicated by the dashed line in the right panel of **Figure 5.5**, it is critical that player 2 assumes that a player 1 of type L is most likely to deviate from action A. Given this assumption, response D is an equilibrium response by player 2, and neither the H nor the L type player 1 would find deviation profitable.

The laboratory investigation of this game presents nested behavioral issues. First, does the principle of sequentiality have any behavioral appeal, i.e., do humans tend to select either or both of the equilibria just discussed? Second, given that sequentiality has some behavioral appeal, which of the two equilibria tend to be selected? An "intuitive criterion" equilibrium refinement proposed by Cho and Kreps (1987) suggests that E1 would be selected. This intuitive criterion discriminates among equilibria on the basis of the plausibility of beliefs off the equilibrium path. In the present context, equilibrium E1 is "intuitive" because it is reasonable for player 1 of type L to deviate from a B action. Other things constant, a unilateral deviation by player 1 from action B could possibly increase earnings for player 1 of type L from 100 to 140, but the earnings of a type A player could *never* increase from such a deviation. Equilibrium E2, on the other hand, is "unintuitive" in the sense that it is not plausible to suppose that a

player 1 of type L would most likely deviate from an action A choice. Even under the best of circumstances, earnings for player 1 of type L would fall from 140 to 100. It is more reasonable to believe that player 1 of type H would deviate from action A. But such a belief would break the equilibrium, as both player 2, and player 1 type H would find unilateral deviation profitable.

The point of this exercise is that, despite the labelling of this equilibrium definition as "intuitive", it relies on rather subtle assumptions about anticipated actions. Yet, surprisingly, after some experience with the game, participants (who had no training in game theory at all) tended not only to coordinate on one of the two sequential equilibria, but they overwhelmingly selected "intuitive" equilibria E1. Of 112 signalling games conducted in the last two-thirds of each session, 101 matched equilibrium E1, and only 7 corresponded to E2. Importantly, support for the intuitive criterion is somewhat context specific. Brandts and Holt (1991) also report cases where it does not perform as impressively. Nevertheless, baseline environments supporting these and even more subtle equilibrium refinements have been identified (e.g., Camerer and Weigelt, 1988, and Banks, Camerer and Porter, 1989).

*In some respects, however, game theoretic predictions do not explain human behavior well at all.* A series of experiments investigating performance of Nash equilibrium predictions in the Rubenstein (1982)/Stahl (1972) noncooperative bargaining game provide two examples which illustrate this result. First, fairness or equity concerns impede the attainment of Nash equilibrium predictions in some contexts. Consider the following ultimatum game: Two players bargain over a fixed money prize. For convenience, assume a dollar is divided. Bargaining takes place in a two steps. First, one player (the "chooser") proposes a division of the dollar. Second, the other player (the "decider") elects whether or not to accept the proposal. If the proposal is not accepted then both players earn nothing. In the unique Nash equilibrium for this ultimatum game, the chooser offers a division that gives the decider only \$.01, and takes the remainder. The decider, faced with options of either \$.01 or nothing, accepts the offer. Experimental investigation of this game reveals that the Nash equilibrium does not organize behavioral data well at all. Deciders tend to frequently reject "unfair" offers in excess of about a

60/40 split.<sup>16</sup>

A second instance where human behavior and Nash equilibrium predictions persistently diverge is seen in a finitely repeated version of this game with discounting. Consider, for example, a three-stage version of the above ultimatum game. The first stage proceeds as described above, except that in the event that the decider elects to reject the proposed division, the dollar prize is reduced in value to \$.50, the players switch roles, and a second stage begins. A rejection by the decider in the second stage will again prompt a reversal of roles, cause the prize to shrink again by one half (to \$.25), and initiate a third stage. The game terminates after the third stage, with both players receiving payoffs of 0 in the event of a rejection. The unique, subgame-perfect equilibrium solution to this game is readily apparent via backward induction: In the third stage, the chooser could ask for (and get) slightly less than \$.25. Given this baseline return, proposed divisions in excess of a \$.25/\$.25 split should be rejected in the second stage, implying that a \$.75 /\$.25 proposal in first stage constitutes an equilibrium for the game.<sup>17</sup>

A variety of experiments have been conducted to evaluate performance in variants of this game with differing discount rates and differing numbers of periods. (e.g., Binmore, Shaked and Sutton, 1985; Neelin, Sonnenschien and Speigel, 1988; and Ochs and Roth, 1989). The general result of these experiments is that humans do not tend to be good at backward induction. Rather, the participants tend to settle on a division of the prize in the first stage that gives the decider the portion of the prize that discounts in going to the second stage. In the example, this implies a \$.50/ \$.50 split of the dollar.

Importantly, the principle of backward induction is not devoid of empirical content in this context. Rather, as Harrison and McCabe (1988) report, subgame perfect Nash equilibrium divisions of the pie tend to occur, but only after participants have had considerable experience with the game as a whole, and particularly with the latter

---

<sup>16</sup> Roth, Prasnikar, Okuno-Fujiwara and Zamir (1990) provide evidence suggesting that the notion of a minimum acceptable division may vary across cultures. These authors conducted ultimatum games in the United States (Pittsburgh), Israel, Japan and Yugoslavia. Participants in Israel and Japan made much less equitable proposals than did participants in the U.S. or Yugoslavia, but there were no significant differences in decider acceptance rates across the countries.

<sup>17</sup> There also exist an infinite number of Nash equilibria that are not subgame perfect. These equilibria depend on threats of plays off the equilibrium path that are not credible, in the sense that they are not equilibrium plays.

stages of the game. In what has come to be termed the "swing-back" hypothesis, participants appear to learn the Nash equilibrium recursively, appreciating first the Nash equilibrium for the final stage game, and then the equilibrium for the second to last stage, and etc. on to the first stage. This "swing-back" effect has been observed in a variety of other laboratory contexts, including a series of thirty 10-stage repeated prisoner dilemma games, reported by Selten and Stoeker (1986), and in a series of iterated 3-period asset market games reported by Anderson, Johnston, Walker and Williams (1991). The effect suggests that equilibrium predictions which rely on backward induction are most likely to apply in contexts where experienced participants have repeatedly observed outcomes in all subgames of the relevant game.

*Various institutional adjustments can very prominently affect outcomes in particular circumstances.* This third conclusion, in some sense, is an analogue to the effects of the trading institution selection on market performance. We illustrate this conclusion by discussing a series of experiments designed to evaluate factors that help resolve equilibrium selection in games with multiple equilibrium. The well-known "Battle-of-the-Sexes" game, illustrated in Figure 5.6, is a standard example of a single stage game characterized by multiple equilibria. In Figure 5.6, the row and column players simultaneously choose actions 1 or 2. From inspection of the payoffs it is readily apparent that there are 2 pure-strategy equilibria in Figure 5.6: [R2, C1], with (row, column) payoffs of (600, 200); and [R1, C2] with payoffs of (200, 600).<sup>18</sup> Now, although the row and column players prefer different equilibria in a single-stage game, both players are better off coordinating on either of the equilibria than they would be in either the upper-left or the lower-right corners. The multiplicity of equilibria presents a formidable behavioral problem. Abdalla, Cooper, DeJong, Forsythe and Ross, 1989 (hereafter ACDFR) report that disequilibrium outcomes occurred in 59 percent of games conducted in the last half of their experimental session.

A number of institutional modifications have been proposed to resolve this equilibrium selection problem. For example, suppose that prior to making a decision for the Figure 5.6 game, the row player is given an outside option of taking a certain payment of 300 in lieu of playing the game. With the addition of this outside option, R1 is a

---

<sup>18</sup> There also exists a mixed strategy equilibrium where each player randomly picks among their strategy choices with probability of .5. Expected payoffs in the mixing equilibria are (200, 200).

**Figure 5.6.**  
**A Battle of the Sexes Game**  
 (Source: Abdalla, Cooper, DeJong, Forsythe and Ross, 1989)

		Column Player's Strategy	
		1	2
Row Player's Strategy	1	0, 0	200, 600
	2	600, 200	0, 0

dominate strategy, and equilibrium [R2, C1] uniquely satisfies a principle of *forward induction* (c.f. Kohlberg-Mertens, 1986). The row player would only forgo the outside option if earnings were increased by playing the **Figure 5.6** game, e.g., if the equilibrium [R2, C1] with payoffs of (600, 200) was selected.<sup>19</sup> ACDFR find that the outside option very effectively resolves the equilibrium selection problem in this context as predicted by forward induction. Over the last half of the games conducted in each experiment session, the addition of the outside option increased selection of the [R2, C1] equilibrium from 19 percent to 72 percent of all outcomes. The addition of an outside option, however, only resolves coordination problems in certain contexts. Consider, for example, the 3x3 coordination game illustrated in **Figure 5.7**. Incentives are somewhat more complex in **Figure 5.7** than in the Battle-of-the-Sexes game. From inspection of **Figure 5.7**, it is evident that there exist two pure-strategy Nash equilibria this game: [R1, C1] and [R2, C2]. Both players strictly prefer equilibrium [R2, C2] to equilibrium [R1, C1], but [R1, C1] is less risky, in the sense that the row (column) player is certain to earn 350 by playing R1 (C1).

As with the Battle-of-the-Sexes game, ACDFR report that this game presents a behavioral coordination problem. Players overwhelmingly select equilibrium [R1, C1] in this game: over the last half of their reported trials [R1, C1] was chosen 70 percent of the time, while [R2, C2] equilibrium was played only 2 percent of the time.

---

<sup>19</sup> The mixing equilibrium mentioned in the preceding note does not affect the uniqueness of [R2, C1] under forward induction, given the outside option of 300. Payoffs to the row player in the mixing equilibrium are 200, less than earnings from taking the option.

Unlike the Battle-of-the-Sexes game, however, the addition of an outside option (of 450) for row does little to improve the selection of the [R2, C2] equilibrium; [R2, C2] was chosen in only 3 percent of the trials in the last half of their experiment. Rather, row typically selected the outside option (73 percent of the time). Notably, although

Figure 5.7.

### A Coordination Game

(Source: Abdalla, Cooper, DeJong, Forsythe and Ross, 1989)

		Column Player's Strategy		
		1	2	3
Row Player's Strategy	1	350, 350	350, 250	1000, 0
	2	250, 350	550, 550	0, 0
	3	0, 1000	0, 0	600, 600

the outside option makes [R2, C2] a unique equilibrium by forward induction, the option does not make R1 a dominated strategy. Thus, it appears that dominance, rather than forward induction organizes the data in this context.

Following theoretical analyses of the effect of communications on equilibrium selection by Farrell and Maskin (1990) and others, ACDFR find another alteration in the structure of the game substantially resolves the coordination problem in both the Battle-of-the-Sexes and the coordination games. Prior to a play of either game, ACDFR allowed the row player to communicate a nonbinding intended play to the column player. The richer message space allowed by these "one-sided, nonbinding communications" very effectively improved performance in both games. In the coordination game, the selection rate for the Pareto-dominant [R2,C2] equilibrium improved to 67 percent, in the last half of relevant sessions. Similarly, one sided, non-binding communications increased the selection rate of the [R2, C1] equilibrium in the Battle-of-the-Sexes game to 96 percent of outcomes in games in the last half of relevant sessions.

Still richer communications are needed to resolve equilibrium selection problems in other environments. For example, Isaac and Walker (1988) found that face-to-face discussions dramatically improve contributions in a public goods experiment. Similarly, Isaac, Ramey and Williams (1984) report that sellers effectively capitalize on

opportunities for explicit conspiracy in posted offer markets. Even face-to-face communications fail to always coordinate behavior, however. Isaac and Plott (1981), for example, report that sellers in a double auction market were generally unable to effect and maintain a conspiracy despite communications between market periods.

### **5.5.3 Summary**

Central experimental results may, for the present purposes, be divided into two basic types: market experiments and tests of noncooperative game theory. Market experiments were initially constructed to evaluate the predictions of competitive price theory, and competitive price and quantity predictions organize experimental data in a very robust set of laboratory circumstances. Manipulations in the trading rules defining the institution of exchange can importantly affect the performance of laboratory markets.

Experimental analysis of the predictions of noncooperative game theory initially grew from a desire to investigate the behavioral properties of the Nash equilibrium prediction in the paradoxical prisoners' dilemma. Similar to market experiment results, baseline game environments can be found which support surprisingly subtle equilibrium predictions. Game theory, however, is unsettled, and many proposed refinements seem not to work. Finally, many of the more interesting issues (both behavioral and theoretic) involve examining institutional features surrounding a particular game. As will be discussed in the next section, it is our perception that many of the more immediate applications of experimental techniques to trade issues will involve consideration of issues specific to games played in a trade context.

## **5.6 Potential Applications of Experimental Methods to Trade Issues**

In this section we suggest two trade topics that might benefit from the application of experimental methods. These topics are merely research suggestions. Although it is not clear that either topic will ultimately merit investigation, we discuss them as a means of evaluating the elements necessary for a productive application of experimental techniques.

Notably, each of the topics mentioned involves issues in international trade negotiations rather than tests of the standard trade

theorems. While a variety of the standard theorems may well merit laboratory investigation, two practical design considerations limit the range of useful projects of this nature. The first is task complexity. An important element of control is that the experiment is simple enough that subjects can understand it in a small portion of the typical 2 to 3 hour laboratory session. A variety of trade models are poor candidates for laboratory investigation, because they involve overwhelmingly complex environments. It is difficult, for example, to imagine participants mastering cost-minimization, profit-maximization, and trade even in a 2-factor, 2-good, 2-country general equilibrium model.

The absence of institutional detail in mainstream trade theory represents a second concern. Much theory is written at a level of generality that ignores the institutional structure of an economy. But if anything has been learned from laboratory investigations, it is that these institutional details affect behavior. Laboratory designs based on *ad hoc* assumptions about the nature of exchange in an economy constitute joint tests of the relevant theory and institutional assumptions. It would be impossible to determine from such a test whether observed behavior was a consequence of the theory or the institutional assumptions. In light of these considerations, consider the following research suggestions.

#### 5.6.1 Self-Enforcing Agreements and Bilateral Trade Negotiations

Consider the problem of tariff-reduction agreements between two countries. A question that has been the focus of considerable theoretical interest has to do with the kinds of agreements between countries that are *self-enforcing*. In a self-enforcing equilibrium, the parties must not only agree on a particular outcome, but they must also be able to support that outcome with credible threats of punishment for deviating from the agreement.

The subject of self-enforcing tariff agreements is particularly interesting due to the growing level of dissatisfaction with GATT's dispute-settlement procedures. If GATT were organized such that potential violators of the Agreement preferred sustained cooperation to the consequences of violations then we could expect few violations. We have in mind a simple model of large countries in which each country prefers to have a high tariff and for the other countries to have no tariffs. Furthermore, each country would prefer "cooperation", in which all countries have low tariffs, to "noncooperation", in which all

countries have high tariffs. We have really just described a prisoners' dilemma type of game in which every player in the game has an incentive to deviate from the agreed-upon tariff level. It is well-known that cooperation can be sustained if players value future cooperation and dread punishment enough.

There exists some disagreement among theorists regarding the minimal conditions necessary for threatened punishments to be credible. Some commentators, for example, would argue that credibility requires that punishments be subgame-perfect, e.g., that the punishments must themselves be equilibria. Others (e.g., Farrell, 1987) would argue that credible punishments must satisfy an even stronger condition of "renegotiation proofness", that the punishment equilibrium is not less desired than the reward equilibria for the punisher. Finally, it may be the case that a variety of elements which are independent of the structure of the equilibria determine the credibility of threats.

Experimental techniques could be used to discriminate among the many theoretical concepts of a self-enforcing agreement to determine which best explains behavior. The results could suggest that GATT complaints could be reduced by revising the nature of the Agreement, particularly its dispute settlement procedures. Davis and Holt (1990) report an experiment conducted in a simple two-stage game design that initiates examination of this issue. The authors' design consists of a 2 person prisoner's-dilemma-type game in a first stage, followed by a 2x2 Battle-of-the-Sexes game in the second stage. The two pure-strategy equilibria in the second stage are structured so that a "cooperative" equilibrium for the two-stage game as a whole involves a play of the preferred but non-equilibrium "cooperative" outcome in the first stage, followed by a "reward" of coordination on the more desirable of the pure-strategy equilibria in the Battle-of-the-Sexes game. This cooperative equilibrium is supported by a "threat" to coordinate on the less desired of the two pure-strategy equilibria in the Battle-of-the-Sexes game. Davis and Holt (1990) report that, given some experience with the game, participants do in fact show some propensity to engage in punish/reward behavior, relative to a baseline design where second-stage payoffs were invariant to choices. Further, although the authors collected only limited data, they find little evidence that alterations in the structure of punishment/reward equilibria affect the incidence of cooperative outcomes in their design.

The relevant baseline environment for applying these issues to problems in trade differs in some important respects from the environment examined by Davis and Holt (1990). Perhaps most prominently, repeated and explicit communications between the

countries is very much a part of the negotiation process in a relevant trade game. As discussed above, communications can powerfully affect equilibrium selection. In fact, a pair of (unreported) pilot experiments by Davis and Holt (1990) provide two suggestions regarding the effects of communications on outcomes. First, the results of a pilot session which allowed participants the opportunity to submit unilateral nonbinding communications of the type discussed by ACDFR suggest that this type of "cheap talk" most likely will not improve either cooperation rates or the administration of rewards. The addition of this restrictive form of communications generated virtually no change in behavior. In a second pilot session, participants were given the opportunity to discuss possible strategies. Results of this second session suggest that the richer multilateral message space allowed by face-to-face communications may very likely improve the incidence of cooperation.

Other alterations in the structure of the game relevant to trade issues may affect the selection of a cooperative equilibrium. For example, both negotiations and agreements between countries occur continuously. The incidence of punish/reward outcomes may evolve more reliably in longer, or even indefinite, repetitions versions of a game of this type.<sup>20</sup>

A number of advantages of this proposed experimental agenda deserve comment. First, the results may easily be calibrated, by comparing results against a baseline treatment where the payoffs in the second stage are invariant to choices. Second, the research questions remain close enough to purely theoretic propositions that the relevant questions may be addressed in a relatively simple environment, unencumbered by complexity that would make it difficult to distinguish behavior from learning. Finally, despite the theoretic nature of the investigation, the agenda examines the effects of institutional modifications specific to issues in trade.

## 5.6.2 Agenda Formation in Multilateral Trade Negotiations

Agenda formation in multilateral trade negotiations represents a second trade topic where experimental methods might be used. While GATT negotiations could include discussions on a variety of

---

<sup>20</sup> Of course, the equilibrium set explodes with increases in the length of the game. But an equilibrium supported by the threat of punishment in a short game will remain an equilibrium in a longer version created by repetition of the short game.

issues, including quotas, intellectual property rights or even environmental concerns, for specificity, let us confine our attention to tariff-reduction negotiations. Given that tariffs impede trade flows, it is not unreasonable to assume that there exists a set of tariff-reduction agreements that would make all countries better off. Countries, however, undoubtedly do not share a common most-preferred agreement within that set, and the diversity of preferences serves as the impetus for bargaining. A bargaining *agenda*, or the order and terms under which various issues are discussed, may importantly influence negotiated outcomes.

Mayer (1981) developed a theoretical model in the context of bilateral tariff-negotiations which showed that the rules for negotiating tariff-reductions were important. He took his cue from the procedures used in the Kennedy and Tokyo Rounds, in which participants agreed first on a tariff-reduction rule and then negotiated the actual cuts. One rule he considered was cutting all tariffs by an equal percentage and then the negotiations would center around the magnitude of the common percentage reduction. The alternative was a harmonizing rule, under which higher tariff rates were to be cut more in order to make rates more equal. The second stage of negotiations would then determine the exact nature of the cuts. Mayer showed that the selection of the rule affected the set of possible equilibria. Casual empiricism suggests some concern among countries regarding agenda changes. In the Kennedy and Tokyo rounds, for example, the U.S. favored the equal percentage rule, as it was beginning negotiations with higher average tariffs than the E.E.C., which favored the harmonizing formula.

A variety of parameters other than the tariff-reduction rule may also affect negotiated outcomes. For example, the decision to open all tariffs to negotiations or to restrict negotiations to a class of products in a round of talks may affect both the probability and the nature of an agreement. Similarly, the decision to ratify sections of the agreement one by one, as they are successfully negotiated, or to ratify the entire agreement after all negotiations are concluded, may affect the agreement. The former method ensures that all will not be lost if future negotiations on different sections are unsuccessful. The latter method has an advantage in that concessions in one area of discussion can be bartered for advantages in another area of discussion without risk. The Uruguay Round was conducted using the latter method and the entire round of negotiations is now in jeopardy due to the U.S.-EC squabble over European agricultural policies.

There already exists an experimental literature on the effects of agenda manipulation on voting outcomes. Results of voting

experiments by Plott and Levine (1978) suggest that, given sufficiently diverse preferences, voting agenda may be manipulated to yield virtually any outcome. Further results by Eckel and Holt (1989) indicate that strategic behavior by experienced participants can counteract the effects of strategic agenda manipulations.

Multilateral negotiations are distinguishable from voting in that compliance with the agreement is voluntary. With voting, the minority opinion is generally compelled to accept majority rule. By contrast, an unsatisfied participant in trade negotiations has the option of withdrawing from the agreement. Since the value of trade liberalization increases with the number of countries taking part, there is some incentive to build a consensus broader than a simple majority.

These questions are, of course, preliminary, and are sketched far too broadly to begin experimentation. A program constructed along these lines, however, has several promising characteristics. Agenda manipulations in multilateral negotiations represent an institutional characteristic perhaps peculiar to trade. Further, these institutional modifications are of the sort that can be cleanly examined in a relatively parsimonious laboratory setting. Keep in mind that the value of an experiment is enhanced if it can be founded on some rival behavioral assumptions or predictions from the relevant theoretical literature. Maintaining control over incentives becomes a further design consideration in experiments involving face-to-face bargaining since anticipated dealings with the other subjects outside of the laboratory could dominate financial incentives.

## 5.7 Conclusions

Experimental methods represent a complement to the other, more standard, empirical methods used by economists. Continuing developments in econometric methods have yielded impressive gains in the amount that can be learned from natural data. There are, however, some issues fundamental to economic theory that simply cannot be evaluated with natural data. The laboratory provides an excellent environment for directly evaluating some of these propositions.

Useful applications of experimental methods to problems in trade are surely numerous and varied. As potentially interesting initial possibilities, we suggest investigation of the effects of some trade-specific institutional modifications of problems that have previously been examined in the laboratory. Analyses of the effects of direct communications on the selection of self-enforcing equilibria, and

the effects of agenda manipulations in a multilateral negotiation context fit this approach. As a closing recommendation, we suggest some reading of the literature prior to initiating an experimental study. It is wasteful to reinvent the wheel, and while we are unaware of any experiments specifically framed as "trade experiments", there does exist a wide variety of papers that address behavioral issues of central concern to problems in trade.
