**Whether crop diversification is a desired strategy for agricultural growth in Bangladesh<sup>1</sup>**

**Sanzidur Rahman**

School of Geography, University of Plymouth, Drake Circus, Plymouth, PL4 8AA; Phone: +44-1752-238411; Fax: +44-1752-233054; E-mail: [srahman@plymouth.ac.uk](mailto:srahman@plymouth.ac.uk)

**ABSTRACT**

*This study aimed at examining the merit of crop diversification as a strategy for agricultural growth in Bangladesh. Specifically, the existence of economies of diversification, scale economies and diversification efficiencies at the farm level were examined using a stochastic input-distance function approach. Results reveal strong evidence of diversification economies amongst most crop enterprises except the combination of modern rice and modern wheat enterprises. Ray economies of scale exist in Bangladeshi cropping system. Also, significant efficiency gains were made from diversification among cropping enterprises. The key policy implication is that crop diversification should be a desired strategy for agricultural growth in Bangladesh. Development of the rural infrastructure is also essential as this will not only improve technical efficiency but may also synergistically promote crop diversification by opening up opportunities for technology diffusion, marketing, storage and resource supplies.*

**JEL classification:** O33; Q18; C21

**Keywords:** Diversification economies, Diversification efficiencies, stochastic input distance function, Crop diversification, Bangladesh.

<sup>1</sup> Paper presented at the 82<sup>nd</sup> Annual Conference of the Agricultural Economics Society held at the Royal Agricultural College, Cirencester, UK during March 31 – April 2, 2008.

## 1. Introduction

The economy of Bangladesh is largely dependent on agriculture. Although, rice production dominates the farming system of Bangladesh, accounting for 70% of the gross cropped area (BBS, 2001), several other crops are also grown in conjunction with rice in order to fulfil a dual role of meeting subsistence as well as cash needs. Since the beginning of 1960s, Bangladesh has pursued a policy of rapid technological progress in agriculture leading to diffusion of a rice-based 'Green-Revolution' technology package. As a result farmers concentrated on producing modern varieties of rice all year round covering three production seasons (*Aus* - pre-monsoon, *Aman* - monsoon and *Boro* - dry winter), particularly in areas that are endowed with supplemental irrigation facilities. This raised concern regarding the loss of crop diversity, consequently leading to an unsustainable agricultural system. For example, Husain et al., (2001) noted that the intensive monoculture of rice led to a displacement of land under low productive non-rice crops such as pulses, oilseeds, spices and vegetables, leading to an erosion of crop diversity, thereby, endangering the sustainability of crop-based agricultural production system. Mahmud et al., (1994: 02) also noted that "the area under non-cereal crops has continuously fallen since late 1970s, mainly due to the expansion of irrigation facilities, which led to fierce competition for land between modern *Boro* season (dry winter) rice and non-cereals". However, an analysis of the level of crop diversification between the two Agricultural Censuses of 1960 and 1996 reveals that the level of crop diversity has actually increased by 4.5 percent over the 36 year period (Table 1). The Herfindahl index of crop diversification is computed at 0.59 in 1960 and 0.54 in 1996. To summarise the main changes between the two census periods were: (i) an increased share of small farms, (ii) a shrinking of average farm size per household, (iii) a decline in total net cropped area, (iv) an increase in cropping intensity, (v) an increased diffusion of modern rice varieties which replaced traditional rice area to a large extent, (vi) a dramatic increase in modern wheat area, and (vii) only a two percent decline in the share of area under non-cereal crops.

There is an apparent paradox in that many non-cereal crops (e.g., potatoes, vegetables, onions and cotton) are more profitable (both in economic and financial terms) than modern rice cultivation, which was mainly attributed to high risk as well as incompatibility of the existing irrigation system to produce non-cereals in conjunction with rice (Mahmud et al., 1994). However, it has been increasingly recognized that, under non-irrigated or semi-irrigated conditions, better farming practices and varietal improvements in non-cereal crops will be more profitable and could lead to crop diversification as a successful strategy for the future growth and sustainability of Bangladeshi agriculture (MoA, 1989; Mahmud et al.,

1994; PC, 1998). The Fifth Five Year Plan (1997–2002) set specific objectives to attain self-sufficiency in foodgrain production along with increased production of other nutritional crops, as well as to encourage the export of vegetables and fruits keeping in view domestic production and need (PC, 1998). The Plan also earmarked Tk 1,900 million (US\$ 41.8 million) accounting for 8.9 percent of the total agricultural allocation to promote crop diversification. Such an emphasis at the policy level points towards the importance of determining the merits of crop diversification at the farm level. We examine this merit in terms of gains in economies of diversification and technical efficiency, so that an informed judgment can be made about the suitability of crop diversification as a desired strategy for promoting agricultural growth in Bangladesh.

Studies on crop diversification in the literature are diverse and focus on its impact either on income or overall production. For example, Guvele (2001) concluded that crop diversification reduces variability in income in Sudan. Van den Berg et al., (2007) concluded that diversification into high-value vegetable crops and away from rice will enable Chinese farms to sustain a reasonable income level given present farm-size distributions. Kar et al., (2004) concluded that crop diversification in upland areas serves as a good measure to mitigate drought as well as increase water use efficiency, while increasing the overall yield of the cropping system in India. However, studies examining the explicit relationship between crop diversification and production efficiency at farm level are few, with mixed conclusions. For example, Coelli and Fleming (2004) concluded that crop diversification significantly improves technical efficiency in Papua New Guinea farms, whereas Llewelyn and Williams (1996) and Haji (2007) concluded that crop diversification significantly reduces technical efficiency in Indonesian farms and allocative and economic efficiency in Ethiopian farms, respectively. It is expected that individual economies within the developing world are unlikely to have a uniform relationship between crop diversification and production efficiency. The contrasting evidence provided by the aforementioned studies proves the point. Therefore, it is important to determine the merits of crop diversification case by case, particularly when the government of Bangladesh is keen to adopt crop diversification as a strategy for agricultural growth as well as to promote sustainability (MoA, 1998; Mahmud et al., 1994).

Given this backdrop, the study is aimed at examining: (a) the existence of economies of diversification among crop enterprises; and (b) the impact of diversification on technical efficiency in farming in Bangladesh. The present study will, therefore, be a valuable addition

to the source of knowledge on the performance of the agricultural sector, which is largely diversified in nature, such as Bangladesh.

## **2. Methodology**

### **2.1 Data and the study area**

The study is based on farm-level cross section data for the crop year 1996 collected from three agro-ecological regions of Bangladesh. The survey was conducted from February to April 1997. Samples were collected from eight villages of the Jamalpur Sadar sub-district of Jamalpur, representing wet agro-ecology, six villages of the Manirampur sub-district of Jessore, representing dry agro-ecology, and seven villages of the Matlab sub-district of Chandpur, representing wet agro-ecology in an agriculturally advanced area. A multistage random sampling technique was employed to locate the districts, then the *Thana* (sub-districts), then the villages in each of the three sub-districts, and finally the sample households. A total of 406 households<sup>2</sup> from these 21 villages were selected. Detailed crop input-output data at the plot level for individual farm households were collected for ten crop groups<sup>3</sup>. The dataset also includes information on the level of infrastructural development<sup>4</sup> and soil fertility determined from soil samples collected from representative locations in the study villages<sup>5</sup>.

### **2.2 Analytical framework**

Sources of productivity growth can be decomposed into two principal components: technical efficiency (TE) and technical change (TC). TE can be interpreted as a relative measure of managerial ability for a given level of technology, whereas TC evaluates the

---

<sup>2</sup> The sample households were selected based on the information on the total number of households including their land ownership categories, which were obtained from BRAC (a national non-governmental organization). Then a stratified random sampling procedure was applied using a formula from Arkin and Colton (1963) that maximizes the sample size with a 5% error limit. Farm size categories (large, medium, and small farmers) were used as the strata (for details, see Rahman, 1998).

<sup>3</sup> The crop groups are: traditional rice varieties (Aus – pre-monsoon, Aman – monsoon, and Boro – dry seasons), modern/high yielding rice varieties (Aus, Aman, and Boro seasons), modern/high yielding wheat varieties, jute, potato, pulses, spices, oilseeds, vegetables, and cotton. Pulses in turn include lentil, mungbean, and gram. Spices include onion, garlic, chilli, ginger, and turmeric. Oilseeds include sesame, mustard, and groundnut. Vegetables include eggplant, cauliflower, cabbage, arum, beans, gourds, radish, and leafy vegetables.

<sup>4</sup> A composite ‘index of underdevelopment of infrastructure’ was constructed using the cost of access approach. A total of 13 elements are considered for its construction. These are primary market, secondary market, storage facility, rice mill, paved road, bus stop, bank, union office, agricultural extension office, high school, college, thana (sub-district) headquarters, and post office (see Ahmed and Hossain, 1990 for construction details).

<sup>5</sup> The ‘soil fertility index’ was constructed from test results of soil samples collected from the study villages during the field survey. Ten soil fertility parameters were tested. These are soil pH, available nitrogen, available potassium, available phosphorus, available sulphur, available zinc, soil texture, soil organic matter content, cation exchange capacity of soil, and electrical conductivity of soil (for details of sampling and tests, see Rahman and Parkinson, 2007 and Rahman, 1998).

effect on productivity arising from the adoption of new or improved production processes (Bravo-Ureta et al., 2007). The gains in TE are derived from improvements in decision making, which in turn are assumed to be linked to a host of socio-economic conditions, e.g., knowledge, education, and experience. On the other hand, TC relates to investment in research and technology (Nishimazu and Page, 1982 cited in Bravo-Ureta et al., 2007). In this study, we are interested in examining whether crop diversification leads to gains in TE (i.e., diversification efficiencies), as well as whether diversification into various crop enterprises lead to gains in economies of scale (i.e., diversification economies).

To examine the existence of diversification economies and diversification efficiencies, a multi-output, multi-input production technology specification is required as opposed to the commonly used single-output, multi-input production technology. The use of a distance function approach (either output-orientated or input-orientated) circumvents this problem and can be analyzed using either parametric or non-parametric methods. Also, the main advantage of a distance function approach is that production frontier can be estimated without assuming separability of inputs and outputs (Kumbhakar, et al., 2003). We select the use of an input-orientated stochastic distance function to address these research questions. This is because, in an economy like Bangladesh, inputs are highly scarce, particularly the land input. Therefore, it is justifiable to assume that inputs are the main decision variables.

We begin by defining the production technology of the farm using the input set,  $L(y)$ , which represents the set of all input vectors,  $x \in R_+^K$ , which can produce the output vector  $y \in R_+^M$ . That is,

$$L(y) = \{x \in R_+^K : x \text{ can produce } y\} \quad (1)$$

The input-distance function is then defined on the input set,  $L(y)$ , as

$$D_I(x, y) = \max\{\rho : (x/\rho) \in L(y)\} \quad (2)$$

$D_I(x, y)$  is non-decreasing, positively linearly homogenous and concave in  $x$ , and increasing in  $y$ . The distance function,  $D_I(x, y)$ , will take a value which is greater than or equal to one if the input vector,  $x$ , is an element of the feasible input set,  $L(y)$ . That is,  $D_I(x, y) \geq 1$  if  $x \in L(y)$ . Furthermore, the distance function will take a value of unity if  $x$  is located on the inner boundary of the input set.

### 2.3 *Economies of diversification*

Coelli and Fleming (2004) presented a measure of economies of diversification for Papua New Guinea farmers relative to an input distance function which, in principle, can be conceived of as the lower-bound estimate of the traditional cost function measure of scope

economies. The partial derivative of the input distance function (defined in the previous section) with respect to the  $i$ th output is generally negative, implying that the addition of an extra unit of output, with all other variables held constant, reduces the amount by which we need to deflate the input vector to put the observation onto the efficient frontier. Thus, the second cross partial derivative of the input distance function with respect to output needs to be positive to provide evidence of economies of diversification. That is, economies of diversification exist between outputs  $i$  and  $j$  if (Coelli and Fleming, 2004):

$$\frac{\partial^2 D}{\partial Y_i \partial Y_j} > 0, \quad i \neq j, \quad i, j = 1, \dots, m. \quad (3)$$

#### 2.4 *Diversification efficiencies*

In addition to the examination of diversification economies, another key question of interest is to investigate whether farming inefficiencies are related to the degree of diversification (or specialization), since the literature on this issue is mixed. Specialization of farming activity may lead to lower inefficiency or vice versa. The expectation is that specialization in production leads to efficiency gains in the division of labour and management of resources (Coelli and Fleming, 2004). Diversification efficiency, which works in the opposite direction to specialization efficiencies, may be derived from intimate knowledge of farmers' yet uncertain production environment and the ability to adjust their labour and other resources to various farming activities.

Two classes of variables can be used to represent the specialization variable. The Herfindahl index, which is based on the area allocated to a particular enterprise (Llewelyn and Williams, 1996) or the Ogive index, which is defined as a concentration of output shares of various enterprises (Coelli and Fleming, 2004). The Herfindahl index is represented as:

$$DV = \sum_{i=1}^n P_i^2, \text{ where } P_i \text{ is the proportion of farm area involved in a particular enterprise. The}$$

value of Herfindahl index ranges between 0 and 1 with 0 denoting perfect diversification and 1 perfect specialization. In this study, we have selected the Herfindahl index of crop diversification<sup>6</sup>. The justification is that land is the scarcest input in Bangladesh compared to any other resource requirements. The land-person ratio is one of the lowest in the world, estimated at only 0.12 ha (FAO, 2001).

---

<sup>6</sup> We have also analysed the data using the Ogive index of output concentration, which provided almost identical results.

## 2.5 *Other factors explaining efficiencies*

In addition to variables representing crop diversification (or specialization), a number of other explanatory factors representing farmers' socio-economic circumstances may affect efficiency. These are: amount of land owned by the farmer, farmers' education and farming experience, family size, extension contact, index of infrastructure development (defined in footnote 3), index of soil fertility (defined in footnote 4), and the proportion of non-agricultural income of the household. Choice of these variables is based on the existing literature and the justification for their inclusion is briefly discussed as follows.

In Bangladesh, land ownership serves as a surrogate for a number of factors as it is a major source of wealth and influences crop production. The size-productivity relationship in Bangladesh varies across regions depending on the level of technological development and environmental opportunities. The relationship is positive in technologically advanced regions, whereas the classic inverse relationship still exists in backward areas (Toufique, 2001). We included the 'amount of land owned' variable to test whether farm size influences technical efficiency.

Use of the education level of farmer as a technical efficiency shifter is fairly common (e.g., Asadullah and Rahman, 2008; Wang et al., 1996; Wadud and White, 2000). The education variable is also used as a surrogate for a number of factors. At the technical level, access to information as well as capacity to understand the technical aspects related to crop production is expected to improve with education, thereby, influencing technical efficiency. The justification for including farming experience is straightforward. Experienced farmers are more likely to be wiser in decisions regarding the use and allocation of scarce inputs.

According to Chayanovian theory of the peasant economy, higher subsistence pressure increases the tendency to adopt new technology and this has been found to be the case in Bangladesh (Hossain, et al., 1990). The subsistence pressure variable (defined as family size per household) was incorporated to test whether it influences technical efficiency as well.

Agricultural extension can be singled out as one of the most important sources of information dissemination directly relevant to agricultural production practices, particularly in nations like Bangladesh where farmers have very limited access to information. This is reinforced by the fact that many studies found a significant influence of extension education on adoption of modern technologies (e.g., Baidu-Forson, 1999; and Adesina and Zinnah, 1993). Therefore, this variable was incorporated to account for its influence on technical

efficiency in order to make a case for strengthening extension services and networks, if its coefficient shows positive sign.

The level of rural infrastructure is a key limiting factor in the development of Bangladeshi agriculture (Ahmed and Hossain, 1990). Areas with better infrastructure can realize higher productivity levels than underdeveloped areas for several reasons. For example, extension information reaches them more easily, and/or delivery of modern inputs such as fertilizers and pesticides is timelier. Soil fertility is also a key factor that exerts a positive influence on productivity (e.g., Rahman, 2005; Rahman and Parkinson, 2007). The indices of ‘underdevelopment of rural infrastructure’ and ‘soil fertility’ were incorporated to test their independent influence on technical efficiency.

The percentage of income earned off-farm was included to reflect the relative importance of non-agricultural work in these farm households. Household with a higher share of non-agricultural income are reported to operate at lower level of technical efficiency (e.g., Ali and Flinn, 1989; Wang et al., 1996).

### 3. The empirical model

A multi-output, multi-input stochastic distance function was used to compute the farm specific technical efficiency index. The empirical model is specified using a translog stochastic input distance function allowing for all possible interactions. All the variables were mean-corrected prior to estimation, so that the coefficients of the first-order terms can be directly interpreted as elasticities or marginal effects. The translog stochastic input distance function, dropping the  $j^{\text{th}}$  subscript for individual farms, is specified as:

$$\ln d = \alpha_0 + \sum_{i=1}^7 \alpha_i \ln X_i + \frac{1}{2} \sum_{i=1}^7 \sum_{j=1}^7 \alpha_{ij} \ln X_i \ln X_j + \sum_{k=1}^4 \beta_k \ln Y_k + \frac{1}{2} \sum_{k=1}^4 \sum_{l=1}^4 \beta_{kl} \ln Y_k \ln Y_l + \sum_{i=1}^7 \sum_{k=1}^4 \tau_{ik} \ln X_i \ln Y_k \quad (4)$$

where Xs are inputs and Ys are outputs. The seven inputs used in the analyses are:  $X_1$  = land under all crops (ha),  $X_2$  = amount of fertilizers (kg),  $X_3$  = amount of total (family supplied + hired) labour (person-days),  $X_4$  = animal power services (animal-pair days),  $X_5$  = irrigation (taka),  $X_6$  = pesticides (taka) and  $X_7$  = seeds (taka). The four outputs are:  $Y_1$  = traditional rice (kg),  $Y_2$  = modern rice (kg),  $Y_3$  = modern wheat (kg), and  $Y_4$  = cash crops<sup>7</sup> (includes jute, cotton, oilseeds, spices, pulses, potatoes, and vegetables) (taka).

---

<sup>7</sup> The gross value of each output is used to construct this compound (aggregate) variable, and is expressed as Taka per farm.

Following Coelli and Perelman (1999), we set  $-\ln d = v - u$ , and impose the restriction required for homogeneity of degree +1 in inputs ( $\sum_{i=1}^7 \alpha_i = 1$ ) to obtain the estimating form of the stochastic input distance function (i.e., normalizing the input vectors by any one of the inputs, specifically the land input  $X_1$ ):

$$-\ln X_1 = \alpha_0 + \sum_{i=2}^7 \alpha_i \ln \left( \frac{X_i}{X_1} \right) + \frac{1}{2} \sum_{i=2}^7 \sum_{j=2}^7 \alpha_{ij} \ln \left( \frac{X_i}{X_1} \right) \ln \left( \frac{X_j}{X_1} \right) + \sum_{k=1}^4 \beta_k \ln Y$$

$$+ \frac{1}{2} \sum_{k=1}^4 \sum_{l=1}^4 \beta_{kl} \ln Y_k \ln Y_l + \sum_{i=2}^7 \sum_{k=1}^4 \tau_{ik} \ln \left( \frac{X_i}{X_1} \right) \ln Y_k + v - u \quad (5)$$

where the  $v$ s are assumed to be independently and identically distributed with mean zero and variance,  $\sigma_v^2$ ; and the  $u$ s are technical efficiency effects that are assumed to be identically distributed such that  $u$  is defined by the truncation at zero of the normal distribution with unknown variance,  $\sigma_u^2$ , and unknown mean,  $\mu$ , defined by:

$$\mu = \delta_0 + \sum_{m=1}^9 \delta_m Z_m \quad (6)$$

where  $Z_1$  = amount of land owned (ha),  $Z_2$  = education of farmer (years of completed schooling),  $Z_3$  = experience of farmer (years),  $Z_4$  = family size (persons),  $Z_5$  = index of underdevelopment of infrastructure (number),  $Z_6$  = index of soil fertility (number),  $Z_7$  = extension contact dummy (1 if had any contact (including training) in past one year, 0 otherwise), and  $Z_8$  = share of non-agricultural income (percent) and  $Z_9$  = Herfindahl index of crop diversification (number).

We follow Battese and Corra (1977) in replacing the variance parameters,  $\sigma_v^2$  and  $\sigma_u^2$ , with  $\gamma = \frac{\sigma_u^2}{(\sigma_v^2 + \sigma_u^2)}$  and  $\sigma_s^2 = \sigma_v^2 + \sigma_u^2$  in the estimating model. The input distances<sup>8</sup> are predicted as (Coelli and Perelman, 1999):  $d = E[\exp(u) | e]$ , where  $e = v - u$ . Estimates of the parameters of the model were obtained using maximum likelihood procedures, detailed by Coelli and Perelman (1999). STATA Software Version 8 was used for the analyses (Stata Corp, 2003).

#### 4. Results

Summary statistics of the variables used in the analysis are presented in Table 2. The average farm size is 0.98 ha; the amount of land owned per farm is 0.65 ha; the average level of

---

<sup>8</sup> The inverse of these input distances are the technical efficiency scores of each individual farms.

education is less than four years; experience in farming is 26 years; average family size is six persons; 22 percent of income is derived off-farm; and only 13 percent of farmers have had contact with extension officers during the past year. The computed Herfindahl index of crop diversification ranges from 0.18 to 1.00 with mean score of 0.60 indicating strong presence of diversification among enterprises.

The results of the maximum likelihood estimation (MLE) of the stochastic input distance function model are presented in Table 3. Two sets of hypotheses were tested using the Likelihood Ratio tests. First, we tested for the presence of inefficiencies and the null hypothesis ( $H_0: \mu = \gamma = 0$ ) was rejected at the 1 per cent level of significance, indicating that the MLE is a significant improvement over an OLS specification and inefficiencies are present in the model. The calculated value of the test statistic is 71.67, which is greater than the critical value obtained from Table 1 of Kodde and Palm (1986) with three restrictions. Second, we tested the joint significance of all the variables including crop diversification index and the null hypothesis ( $H_0: \delta_m = 0$  for all  $m$ ) was rejected at the 1 per cent level of significance. The calculated value of the test statistic is 33.28, which is greater than the critical value of  $\chi^2$  with 9 restrictions, implying that the inclusion of these variables to explain inefficiency is justified.

One-third of the estimated coefficients are significantly different from zero at the 10 percent level at least. The signs of the coefficients on the first order terms of the input and output variables are consistent with theory. For example, a positive coefficient on any input variable implies substitutability of that input with land. On the other hand, a negative coefficient on any output variable implies that a reduction in land area is positively associated with a reduction in that output. The coefficients on a number of interaction variables (second order terms) are also significantly different from zero, thereby, confirming non-linearities in the production process, and hence, justifies the use of the flexible translog specification. The sum of the coefficients on four output variables (traditional rice, modern rice, modern wheat and cash crops) is 0.78. The inverse of this figure (1.28) provides a measure of ray scale economies (at the sample means), suggesting increasing returns to scale. The implication is that the farmers are likely to benefit from significant economies of scale (Coelli and Fleming, 2004).

Prior to the discussion of the evidence of diversification economies, we briefly report the technical efficiency scores. A plot of the distribution of technical efficiency scores is presented in Figure 1. The efficiency scores range from 33 to 98 percent with a mean score of

84 percent<sup>9</sup>. This estimated mean level of technical efficiency is higher than the estimates of technical efficiency for producing only rice crops in Bangladesh. For example, technical efficiency of rice production is estimated at 69.4 percent (Coelli et al., 2002) and 78.9 percent (Wadud and White, 2000) in Bangladesh. The implication is that, although there is substantial opportunity to expand crop output without additional resources, the results of earlier studies on Bangladesh somewhat overstated the scope to expand overall output by concentrating on rice crops only, which corroborates with the findings of Bravo-Ureta et al., (2007). Bravo-Ureta et al., (2007), using a meta-analysis of 167 efficiency studies conducted worldwide, concluded that frontier models with grain crops present, on average, lower mean technical efficiency scores than those for ‘other crops’, ‘dairy and cattle’, or ‘whole farm’ categories. The distribution of efficiency score has a long tail at the lower end of the efficiency spectrum (Figure 1). About 25 percent of the farmers are producing at an efficiency level of less than 60 percent. However, two-thirds of the farmers are producing at the top decile range (90 percent and above), which is encouraging.

#### **4.1 Economies of Diversification**

Following Coelli and Fleming (2004), we calculate the measure of diversification economies (defined in Eq. 3) using the coefficient estimates reported in Table 3 for each pair of crop enterprises (outputs) at the mean values of the sample data<sup>10</sup>. The result of this exercise is presented in Table 4. Unlike Coelli and Fleming (2004), we find strong evidence of economies of diversification across most crop combinations except modern rice and modern wheat crops. The possible explanation is that, modern rice (particularly, the *Boro* season rice) and modern wheat are grown in the same winter season and, therefore, there are potentially clashes with resource allocation requirements, particularly the land and labour inputs. Since, double log specification is used to compute these diversification economies, the coefficients can be read as diversification elasticities. For example, the diversification economies between traditional and modern rice is estimated at 0.02. The implication is that a one percent increase in traditional rice output will reduce the marginal use of inputs for producing modern rice by 0.02 percent. Given the estimated coefficients, it seems that the economic gain of diversification is highest with the combination of modern rice and cash crops, as expected.

#### **4.2 Diversification efficiencies**

---

<sup>9</sup> The correlation between the computed technical efficiency scores from model with the Herfindahl index and the model with the Ogive index is estimated at 0.98 ( $p < 0.01$ ). Therefore, we have decided to report only the results of the model using the Herfindahl index.

<sup>10</sup> Details of the derivation of these estimates and their respective standard errors are presented in Appendix A.

The results of the inefficiency effects model are presented in the lower panel of Table 3. It is clear from Table 3 that significant diversification efficiency exists in Bangladeshi crop production. The positive coefficient on the Herfindahl index indicates that technical inefficiency is positively associated with specialization, which implies that crop diversification, therefore, significantly improves technical efficiency. This result is consistent with Coelli and Fleming (2004) but not with Llewelyn and Williams (1996) and Haji (2007).

Table 5 presents input use rates classified by the level of farm diversification. We designated farms below the mean level of the Herfindahl index of the sample ( $<0.60$ ) as ‘diversified farms’ and farms with the Herfindahl index  $>0.90$  as ‘specialized farms’, who were largely modern rice producers. It is clear from Table 5 that the operational size of diversified farms is significantly higher and the use rates of inputs per hectare, except irrigation and seeds, are significantly lower. The use rates of labour, fertilizer and pesticide are 35, 24 and 125 percent lower among diversified farms compared with those of specialized farms. Although, gross value of output is significantly higher for specialized farms, the profits are similar between specialized and diversified farms, due to significantly lower use of inputs by the latter. It is also clear from Table 5 that, technical efficiency is significantly higher for diversified farms. The mean technical efficiency score for specialized farms is computed at 0.52 compared to 0.97 for the diversified farms. This finding also implies that the diversified farms are already operating at a very high level of efficiency with very little to improve through resource reallocation.

Farmers located in regions endowed with better infrastructure are more technically efficient, as expected<sup>11</sup> (Table 3). The implication is that technical efficiency would be adversely affected by not having inputs to use at the correct time, or not at all. This finding is consistent with the existing literature (e.g., Ali and Flinn, 1989; Wang et al., 1996; Rahman, 2003).

## **5. Discussion and policy implications**

The aim of this study is to examine whether crop diversification is a desired strategy for agricultural growth in Bangladesh. Specifically, we investigated the existence of economies of diversification and diversification efficiencies in farming systems that produce a mix of crops to cover subsistence as well as cash needs. We find strong evidence of diversification economies in most of the crop enterprises, except the modern rice and modern wheat combination. In other words, specialization (i.e., intensive modern rice monoculture in

---

<sup>11</sup> This index is constructed as the “underdevelopment of infrastructure”. Therefore, a positive sign on the coefficient of this variable implies a positive impact on technical efficiency.

our case) has two effects on overall productivity. The first is the negative impact on productivity via loss of diversification economies. The second effect is to reduce overall productivity via loss of diversification efficiencies (Coelli and Fleming, 2004). The economy of diversification perhaps is realized in two ways: (a) by effective use of household labour in lean seasons and avoiding bottlenecks in labour usage; and (b) by using less purchased inputs, particularly pesticides and fertilizers. When a farm diversifies into a combination of subsistence and cash crop production, the farmer uses the opportunity to select enterprises that complement each other, given the nature of seasonality in demand for labour in particular. For instance, modern rice production exerts significant pressure on labour requirements during transplanting and harvesting seasons, whereas traditional rice is largely broadcasted and uses large amounts of labour during the harvesting period only. Evidence of diversification economy observed between traditional and modern rice enterprises is largely due to the practice of producing traditional and modern rice in the main growing season, the Aman season (monsoon season), where the irrigation requirement for the latter is substituted to a large extent by rainfall. Also, labour requirements for both can be economised. This phenomenon perhaps partly explains stagnancy in the overall coverage of modern rice at 69 percent of the total rice area, and the figure is even lower at only 43 percent during the Aman season (BBS, 2001).

The cropping system in Bangladesh is largely influenced by access to water. The cropping pattern can be broadly classified into cropping under rainfed and irrigated conditions, which again vary according to the degree of seasonal flooding. As mentioned earlier, an apparent paradox exists in that, although many non-cereals are more profitable than producing modern rice, their expansion has stagnated due to the incompatibility of the existing modern irrigation systems (Mahmud et al., 1994). In fact, areas where modern irrigation is non-existent or unreliable, modern wheat is the desired crop and provides higher profitability (Morris et al., 1996). In general, the proportion of non-cereal crops is lower under irrigated conditions as compared to rainfed conditions (Mahmud et al., 1994). The sample households of this study also demonstrated that the cropping system is highly diverse in areas with poor irrigation facilities. For example, cropping diversity is significantly lower in the Comilla region in comparison to the Jamalpur and Jessore regions. This is because some of the villages in Comilla region fell within the Meghna-Dhonagoda Flood Control, Drainage and Irrigation (FCD/I) project, which resulted in the dominance of modern rice monoculture throughout the crop year because of the assured availability of water for irrigation at a cheap rate (Rahman, 1998).

An important issue that limits the scope to expand non-cereals is the existence of the price risk associated with uncertainties in marketing, particularly for perishable crops such as vegetables. In fact, annual variability in harvest prices is as high as 15–25 percent for most fruits and vegetables (including potatoes) and 20–40 percent for spices as compared to only 5–6 percent for cereals (Mahmud et al., 1994). This perhaps explains the decline in the area under spices between the census years (Table 1). Mahmud et al., (1994) further noted that the price shock is most severe at the level of primary markets during harvest seasons. Delgado (1995) stressed the need for addressing marketing issues and constraints as a priority option to promote agricultural diversification in sub-Saharan African regions. This is because in the absence of improved markets, the agricultural sector is likely to suffer from demand constraints as well as a weak supply response, thereby, affecting growth. One way to lower the price risk is through improvements in marketing, which in turn depends on the development of the rural infrastructure. The results of this study clearly reveal that infrastructure significantly improves technical efficiency, which is consistent with the existing literature (e.g., Ali and Flinn, 1989; Wang et al., 1996; Coelli et al., 2002; Rahman, 2003; and Wadud and White, 2000). Infrastructure development in turn may also open up opportunities for marketing, storage and resource supplies, which would complement crop diversification. For example, Ahmed and Hossain (1990) concluded that farms in villages with relatively developed infrastructure use relatively greater amounts of fertilizer and market a higher percentage of their agricultural products in Bangladesh. Evenson (1986) noted a strong relationship between roads and increased agricultural production in the Philippines. He claimed that a 10 percent increase in roads would lead to a 3 percent increase in production in the Philippines. Ahmed and Donovan (1992: 31) concluded that “the degree of infrastructural development is in reality the critical factor determining the success of market-oriented sectoral and macroeconomic policies in the developing world”.

Also, it should be noted that the non-cereals produced by most farmers comprised largely traditional varieties, which are low yielding. Strategy to improve varieties of non-cereals, therefore, provides further potential to improve productivity gains from diversification. Conventionally, the R&D activities in Bangladesh are largely concentrated on developing modern rice varieties to the neglect of most other crops. Among the non-cereals, modern technology is only well established in potato cultivation (Mahmud et al., 1994). The Bangladesh Agricultural Research Institute (BARI) is entrusted with the responsibility of developing modern varieties of all cereal and non-cereal crops except rice and jute. To date, a total of 131 improved varieties of various cereal and non-cereal crops have been developed

and released by BARI, with two-thirds of these only being released from 2006 (Hossain, et al., 2006). However, there is a need to examine the impact of these new releases on farmers' portfolios of crop choices at the farm level, because the technical and socio-economic constraints on the diffusion of these technologies remain unexplored and less understood (Mahmud et al., 1994).

The results of this study also reveal that increasing returns to scale are evident in Bangladeshi crop production. The implication is that Bangladeshi farmers could gain by increasing their farm sizes. Conventionally, either constant or decreasing returns to scale in Bangladesh are usually reported in the literature, which, however, remains limited to examining rice production only (e.g., Wadud and White, 2000; Coelli et al., 2002; Rahman, 2003; Asadullah and Rahman, 2008).

A clear policy implication that emerges from the results of this study is that crop diversification should be a desired strategy to promote agricultural growth in Bangladesh, as it has a positive impact on resource economy as well as technical efficiency. The challenge, however, remains how to succeed with this strategy. The thrust at the planning level to promote diversification and allocating 8.9 percent of total agricultural budget during the Fifth Five Year Plan (1997–2002) is a step in the right direction. Also, another key policy implication is investment in the development of rural infrastructure, which will not only increase the technical efficiency of the farmers but also complement crop diversification by improving opportunities for technology diffusion, marketing, storage and resource supplies.

Note: Profits = (gross value of output – variable cost of all inputs)

\*\*\* = significant at 1 percent level ( $p < 0.01$ )

Figure 1. Distribution of technical efficiency indices.

## Appendix A

After estimation, Eq. (5) can be written as:

$$\begin{aligned}
 -\ln X_1 = & \hat{\alpha}_0 + \sum_{i=2}^7 \hat{\alpha}_i \ln\left(\frac{X_i}{X_1}\right) + \frac{1}{2} \sum_{i=2}^7 \sum_{j=2}^7 \hat{\alpha}_{ij} \ln\left(\frac{X_i}{X_1}\right) \ln\left(\frac{X_j}{X_1}\right) + \sum_{k=1}^4 \hat{\beta}_k \ln Y \\
 & + \frac{1}{2} \sum_{k=1}^4 \sum_{l=1}^4 \hat{\beta}_{kl} \ln Y_k \ln Y_l + \sum_{i=2}^7 \sum_{k=1}^4 \hat{\tau}_{ik} \ln\left(\frac{X_i}{X_1}\right) \ln Y_k + \hat{v} - \hat{u} \quad (A1)
 \end{aligned}$$

Replacing  $(\hat{v} - \hat{u})$  with  $-\ln D$  gives:

$$\begin{aligned}
 -\ln X_1 = & \hat{\alpha}_0 + \sum_{i=2}^7 \hat{\alpha}_i \ln\left(\frac{X_i}{X_1}\right) + \frac{1}{2} \sum_{i=2}^7 \sum_{j=2}^7 \hat{\alpha}_{ij} \ln\left(\frac{X_i}{X_1}\right) \ln\left(\frac{X_j}{X_1}\right) + \sum_{k=1}^4 \hat{\beta}_k \ln Y \\
 & + \frac{1}{2} \sum_{k=1}^4 \sum_{l=1}^4 \hat{\beta}_{kl} \ln Y_k \ln Y_l + \sum_{i=2}^7 \sum_{k=1}^4 \hat{\tau}_{ik} \ln\left(\frac{X_i}{X_1}\right) \ln Y_k - \ln D \quad (A2)
 \end{aligned}$$

Re-arranging gives:

$$\begin{aligned}
 \ln D = & \hat{\alpha}_0 + \sum_{i=2}^7 \hat{\alpha}_i \ln\left(\frac{X_i}{X_1}\right) + \frac{1}{2} \sum_{i=2}^7 \sum_{j=2}^7 \hat{\alpha}_{ij} \ln\left(\frac{X_i}{X_1}\right) \ln\left(\frac{X_j}{X_1}\right) + \sum_{k=1}^4 \hat{\beta}_k \ln Y \\
 & + \frac{1}{2} \sum_{k=1}^4 \sum_{l=1}^4 \hat{\beta}_{kl} \ln Y_k \ln Y_l + \sum_{i=2}^7 \sum_{k=1}^4 \hat{\tau}_{ik} \ln\left(\frac{X_i}{X_1}\right) \ln Y_k + \ln X_i \quad (A3)
 \end{aligned}$$

Taking the first partial derivative of Eq. (A3) with respect to  $Y_k$  gives:

$$\frac{\partial \ln D}{\partial \ln Y_k} = \sum_{k=1}^4 \hat{\beta}_k + \frac{1}{2} \sum_{k=1}^4 \sum_{l=1}^4 \hat{\beta}_{kl} \ln Y_l + \sum_{i=2}^7 \sum_{k=1}^4 \hat{\tau}_{ik} \ln\left(\frac{X_i}{X_1}\right) \quad (A4)$$

Taking the second partial derivative of Eq. (A4) with respect to  $Y_l$  (for all  $k \neq l$ ) gives:

$$\frac{\partial \ln D}{\partial \ln Y_k \partial \ln Y_l} = \frac{1}{2} \sum_{k=1}^4 \sum_{l=1}^4 \hat{\beta}_{kl} = \hat{\omega}_{kl} \quad (\forall k \neq l) \quad (A5)$$

The standard error (S.E.) of  $\hat{\omega}_{kl}$  can be obtained by applying the ‘delta method’ as follows.

In view of the central limit theorem, the ‘delta method’ applies to functions of sample mean. Informally, we can say that  $h(\hat{\omega}_{kl})$  is approximately normal with mean  $h(\omega)$  and variance  $|h'(\omega_{kl})|^2 \text{var}(\hat{\omega}_{kl})$  (Pawitan, 2001).

Applying this method, therefore, gives:

$$\text{Var}(\hat{\omega}_{kl}) = \text{Var}\left(\frac{1}{2} \hat{\beta}_{kl}\right) = |h'(\omega_{kl})|^2 \text{var}(\hat{\omega}_{kl}) = \frac{1}{4} \text{Var}(\hat{\beta}_{kl}) \quad (A6)$$

which is equivalent to:

$$\text{S.E.}(\hat{\omega}_{kl}) = \frac{1}{2} \text{S.E.}(\hat{\beta}_{kl}) \quad (A7)$$
