Abstract

Economic viability of the US corn ethanol industry depends on prices, technical and economic efficiency of plants and on continuation of policy support. Public policy support is tied to the environmental efficiency of plants measured as their impact on emissions of greenhouse gases. This study evaluates the environmental efficiency of seven recently constructed ethanol plants in the North Central region of the U.S., using nonparametric data envelopment analysis (DEA). The minimum level of GHG emissions feasible with the available technology is calculated for each plant and this level is used to decompose environmental efficiency into its technical and allocative sources. Results show that, on average, plants in our sample may be able to reduce GHG emissions by a maximum of 6% or by 3,116 tons per quarter. Profit maximizing input and output allocations are also found based on observed prices. The environmentally efficient allocation, the profit maximizing allocation, and the observed allocation for each plant are combined to calculate shadow cost of reducing greenhouse gas emissions. These shadow costs gauge the extent to which there is a trade off or a complementarity between environmental targets and profits. Results reveal that, at current activity levels, plants may have room for simultaneous improvement of environmental efficiency and economic profitability.

Key words: ethanol, data envelopment analysis, life-cycle emissions, environmental efficiency, shadow prices

Introduction

The U.S. corn ethanol industry has benefited from government support due to its potential to achieve a rather wide set of goals: mitigating emissions of greenhouse gases (GHG), achieving energy security (diversifying energy sources), improving farm incomes and fostering rural development among others. Continuation of policy support, however, is being debated due to doubts about the direct and indirect GHG effects of the industry. Moreover, the capacity of the industry to reduce overall GHG emissions per gallon of ethanol produced may also determine the opportunities opened to it in future carbon markets and in the National Renewable Fuel Standard program. This study provides information relevant to these issues by measuring the current environmental performance of the industry in terms of GHG emissions and the economic cost (shadow price) of GHG reductions.

Input requirements and byproducts' yield per gallon of ethanol produced are critical in determining environmental performance. Previous studies have addressed the issue of input requirements and byproducts' yield of ethanol plants. Using engineering data McAloon et al. (2000) and Kwiatkowski et al. (2006) measured considerable improvement in plant efficiency between 2000 and 2006. Shapouri, et al. (2005) reported input requirements and cost data based on a USDA sponsored survey of plants for the year 2002. Wang et al. (2007) and Plevin et al. (2008), reported results based on spreadsheet models of the industry (GREET and BEACCON, respectively.) Pimentel et al. (2005) and Eidman (2007) reported average performances of plants although they do not clearly indicate the sources of their estimates. Finally Perrin et al. (2009) reported

results on input requirements, operating costs, and operating revenues based on a survey of seven dry grind plants in the Midwest during 2006 and 2007.

With the exception of Shapouri et al. (2005) and Perrin et al. (2009) all of these studies reported values corresponding to the average plant rather than to individual plants. In addition, it is generally believed that the industry has become more efficient and technologically homogeneous since 2005. Since the data used in Shapouri et al. (2005) was collected in 2002 it may not be representative of current technologies in the industry. In contrast to Shapouri et al. (2005), Perrin et al. (2009) surveyed plants in operation during 2006 and 2007 and employed a much more restrictive sampling criteria (discussed below) which yielded a modern and technologically homogenous sample of plants. This sample is believed to be more representative of current technologies and is, hence, our data of choice to assess the environmental performance of plants. Based on this data the present study evaluates the environmental efficiency of seven recently constructed ethanol plants in the North Central region of the U.S. The operating profits that may be gained or lost by plants as a consequence of the effort to reach a given environmental target are also calculated and discussed.

Materials and Method

Data

The environmental performance of a plant is evaluated on the basis of emission of greenhouse gases associated with its productive activity. Greenhouse gas emissions from plants are not directly observable, but are rather calculated based on observable inputs and outputs corresponding to each plant. In addition concerns regarding the

environmental impact of ethanol production refer to life cycle¹ GHG emissions and not only those emissions at the processing stage. Therefore we evaluate life cycle GHG emissions associated with observable inputs and outputs. Our observations consist of 33 quarterly reports of input and output quantities and prices from a sample of seven Midwest ethanol plants. Following the non parametric efficiency literature we refer to each observation as a decision making unit (DMU). Plants produce 3 outputs (ethanol, dry distillers grains with solubles (DDGS), and modified wet distillers grains with solubles (MWDGS)) using 7 inputs² (corn, natural gas, electricity, labor, denaturant, chemicals, and "other processing costs").

Ethanol Plants: Characteristics

Table 1 presents some quarterly characteristics of the seven dry grind ethanol plants surveyed. According to Table 1 the plants produced an average rate equivalent to 53.1 million gallons of ethanol per year, with a range from 42.5 million gallons per year to 88.1 million gallons per year. The period surveyed included the third quarter of 2006 until the fourth quarter of 2007 (six consecutive quarters). In addition plants could be differentiated by how much byproduct they sold as DDGS (10% moisture) compared to MWDGS (55% moisture.) Variation on this variable was significant, averaging 54% of

¹ "Life cycle" in this case includes emissions taking place at three stages of the production process: corn production (farmers), ethanol production (biorefinery), and feedlot (byproducts from ethanol plants are given a credit for replacing corn as feed in livestock production).

² Results of our survey contained total expenditures in labor, denaturant, chemicals, and other processing costs. As a result we calculated implicit quantities for these inputs dividing total expenditures by their corresponding price indexes. Labor and management price index associated to the Basic Chemical Manufacturing Industries was obtained from <u>http://www.bls.gov/oes/current/naics4_325100.htm#b00-0002</u>. Denaturant, chemicals and other processing costs were calculated based on the Producer Input Price Index for "All other basic inorganic chemicals", <u>http://www.bls.gov/pPI/</u>.

byproduct sold as DDGS, but ranging from one plant that sold absolutely no byproduct as DDGS to another plant that sold nearly all byproduct (97%) as DDGS.

Finally, Table 1 briefly characterizes plant marketing strategies. In purchasing input feedstock, five of the six plants purchased corn via customer contracts. Similarly, in selling ethanol, five of the six plants used third parties or agents. Byproduct marketing across plants displayed a higher degree of variance. Marketing of DDGS was split fairly evenly between spot markets and third parties/agents. An even higher variability was observed for MWDGS, where no one marketing strategy (spot market, customer contract, or third party/agent) was significantly more prevalent across plants than any other.

Table 2 displays descriptive statistics of inputs used and outputs produced by the 33 DMUs in our sample. As mentioned before the basic observations in this study corresponds to a plant in a given quarter; so two quarters of the same plant are considered as two different observations as are two plants in the same quarter.

Emissions Measurement

A number of computer packages have been developed to facilitate these calculations (Wang et al. 2007; Farrell et al. 2006). We used the Biofuels Energy Systems Simulator³ (BESS). The BESS model includes all GHG emissions from the burning of fossil fuels used directly in crop production, grain transportation, biorefinery energy use, and coproduct transport. All upstream energy costs and associated GHG emissions with production of fossil fuels, fertilizer inputs, and electricity used in the production life cycle are also included. Since these calculations involve modeling of crop production and

³ BESS is a software developed by a team of specialists in the Agronomy Department at the University of Nebraska, Lincoln (Liska, et al, 2009a, 2009b, <u>http://www.bess.unl.edu/</u>)

feedlot and these display regional differences, BESS include regional scenarios and an average scenario for the whole Midwest region. Plants in our sample are scattered across the Midwest and, hence, we have used scenario 2 in BESS "US Midwest average UNL" which is deemed representative of the whole region.

The BESS calculations of GHG emissions associated with a dry mill plant are equivalent to the following linear relationship:

$$GHG_{Mg} = 0.00668274 x_{c} + 0.063015823 x_{NG} + 0.0007445 x_{elect} + 0.000316916 u_{Eth} - 0.4197522186 u_{DDGS} - 0.407868 u_{MWDGS}$$
(1)

Where GHG_{Mg} represents megagrams of life cycle CO2 equivalent greenhouse gases, x_c is bushels of corn used by the plant, u_{DDGS} and u_{MWDGS} are tons of byproduct sold as dried and modified wet respectively by the plant, x_{NG} is the total amount of natural gas used by the plant measured in MMBTUs, x_{elect} is total amount of kilowatt hours (kwh) of electricity used by the plant, and u_{Eth} is the plant's ethanol production in gallons.

Eq. (1) states that a bushel of corn used in an ethanol plant is associated with about 0.0067 megagrams of GHG emitted during the production of that bushel used in the biorefinery. DDGS and MWDGS have a positive and a negative component. The former is due to additional energy used in reducing moisture.⁴ The latter are "credits" attributed to byproducts (i.e. reductions in GHG) due to the replacement of corn that would have been fed to livestock had the byproduct not been sold. The coefficient for ethanol production represents the combination of emissions associated with depreciable capital

⁴ In particular MWDGS require the use of electricity to centrifuge the wet byproduct and DDGS require the use of natural gas for heating and drying the wet byproduct.

(0.0002050) and freight for grain transportation (0.000111916), expressed on a per gallon basis.

Eq. (1) includes outputs $u^{j} = (u_{Eth}^{j}, u_{MWDGS}^{j}, u_{DDGS}^{j})$ and a pollution increasing subset of all inputs used by ethanol plants⁵ denoted by $x_p^j = (x_c^j, x_{NG}^j, x_{elect}^j)$, where subindex p indicates pollutant. We can now re express Eq. (1) in vector notation. To do so we partition inputs and outputs into a column vector of pollution increasing inputs and output $a^{j} = (x_{c}^{j}, x_{NG}^{j}, x_{elect}^{j}, u_{Eth}^{j})'$ and a column vector of pollution reducing byproducts $u_b^j = (u_{MWDGS}^j, u_{DDGS}^j)'$. The level of greenhouse gas emissions associated with a particular plant *j* as a function of observable inputs and outputs can be expressed as: $GHG^{j} = \alpha a^{j} + \beta u_{h}^{j}$

(2)

Where $\alpha = (0.006682, 0.063015, 0.000744, 0.000316)$ is the 1x4 row vector of coefficients associated with pollution increasing categories a^{j} , and

 $\beta = (-0.419752, -0.407868)$ is the 1x2 row vector of coefficients associated with pollution reducing byproducts u_b^j .

Characterization of Potential Ethanol Technology From Individual Plant Data

Plants are constrained by a technology transforming a vector of N inputs $x = (x_1, x_2, ..., x_N) \in \mathfrak{R}^N_+$ into a vector of M outputs $u = (u_1, u_2, ..., u_M) \in \mathfrak{R}^M_+$. Observed combinations of inputs used and outputs produced (x^j, u^j) are taken to be representative

⁵ As described before ethanol plants use 7 inputs in production. However only three of them increase lifecycle emissions of GHGs: corn, natural gas, and electricity.

points from the feasible ethanol technology. In this study we use data envelopment analysis (DEA) to infer the boundaries of the feasible technology set from the observed points, following the notation in Färe, et al.

Observations from the technology consist of a sample of J DMUs producing M outputs and using N inputs. The production technology can be represented by a graph denoting the collection of all feasible input and output vectors:

$$GR = \left\{ \left(x, u \right) \in \mathfrak{R}_{+}^{N+M} : x \in L(u) \right\}$$

Where L(u), is the input correspondence which is defined as the collection of all input vectors $x \in \mathfrak{R}^{N}_{+}$ that yield at least output vector $u \in \mathfrak{R}^{M}_{+}$.

The frontier of the graph GR and observed levels of inputs and outputs will serve as references for environmental efficiency assessment.

Environmental Efficiency Measurement

A given DMU is deemed more environmentally efficient whenever it chooses a feasible (subject to the graph) combination of inputs and byproducts (DDGS and MWDGS) that results in lower GHG emissions while maintaining its ethanol production level at the observed value denoted by $\overline{u_{Eth}^{j}}$. Fixing ethanol production to its observed level, and assuming variable returns to scale and strong disposability of inputs and outputs the graph can be denoted by:

$$GR^{j}\left(V, S, \overline{u_{Eth}^{j}}\right) = \left\{ \left(x, u\right) : u_{b}^{j} \le zM_{b}, x^{j} \ge zN, zu_{Eth} = \overline{u_{Eth}^{j}}, \sum_{j=1}^{33} z^{j} = 1, j = 1, ..., 33 \right\}$$
(3)

Where z depicts a row vector of 33 intensity variables, M_b is the 33x2 matrix of observed byproducts, u_b^j is the 1x2 vector of observed byproducts corresponding to the jth DMU, N is the 33x7 matrix of observed inputs, , x^j is the 1x7 vector of observed inputs corresponding to the jth DMU, u_{Eth} is the 33x1 vector of observed outputs, and $\overline{u_{Eth}^j}$ is the observed ethanol production by observation j.

We define the set of all combinations of corn, gas, electricity and byproducts that result in lower emissions than those actually produced by the *j*th DMU as:

$$GHG_{g}^{j}\left(x_{p}^{j}, u_{b}^{j}, \overline{u_{Eth}^{j}}\right) = \left\{\left(x_{p}^{j\prime}, u_{b}^{j}\right) : \alpha_{x} x_{p}^{j\prime} + \beta u_{b}^{j\prime} \le \alpha_{x} x_{p}^{j} + \beta u_{b}^{j}\right\}$$
(4)

Where α_x is a subset of the vector α previously defined which does not include the coefficient for ethanol, i.e. $\alpha_x = (0.006682, 0.063015, 0.000744)$ and the rest is as before.⁶

From Eq. (4) we can derive an isopollution line in DDGS and corn space, i.e. combinations of DDGS and corn that result in the same level of emissions keeping everything else constant. Fig. 1 depicts this set graphically in the corn and DDGS space (i.e. keeping everything else in the GHG equation fixed). The set GHG_g^j consists of all those points above the isopollution line as indicated by the arrows with direction northwest.

⁶ We denote the coefficient associated with ethanol by $\gamma = 0.000316$. Ethanol production and its associated coefficient are included in both sets. However, since ethanol is fixed at the observed level $\overline{u_{Eth}^{j}}$, the complete version of the inequality is $\alpha_x x_p^{j'} + \beta u_b^{j'} + \gamma \overline{u_{Eth}^{j}} \le \alpha_x x_p^{j} + \beta u_b^{j} + \gamma \overline{u_{Eth}^{j}}$ which after elimination is equivalent to the expression in (4).

Fig. 1 - Isopollution and Sets

In Fig. 1 the feasible technology set is represented by a graph displaying variable returns to scale and strong disposability of inputs and outputs as indicated by the arrows moving from the frontier $(u_{DDGS} = f(x_c))$ with direction southeast. As clearly seen in Fig. 1, the set GHG_g^j includes combinations outside the graph and hence not attainable by DMUs in the sample. The subset of observations in GHG_g^j that belong to the graph and are hence attainable by DMUs is depicted by the intersection of both sets delimited by the bold lines in Fig. 1:

$$GHG_{g}^{j}\left(x_{p}^{j},u_{b}^{j},\overline{u_{Eth}^{j}}\right) \cap GR\left(V,S,\overline{u_{Eth}^{j}}\right)$$

$$(5)$$

The *j*th DMU could choose any alternative production plan within the area denoted by the bold lines to produce its ethanol production level, achieving a reduction in emissions while simultaneously increasing DDGS or reducing corn or both. In this study, the environmental **technically** efficient projection of a given observation to the boundary of the technology set follows a hyperbolic path defined by equiproportional reductions in inputs and increases in byproducts. The value of the proportionate change necessary to encounter the boundary, ETE_g^j , is defined as the technical environmental efficiency of plant j:

$$ETE_{g}^{j}\left(x_{p}^{j}, u_{b}^{j}, \overline{u_{Eth}^{j}}\right) = \min\left\{\lambda : GHG_{g}\left(\lambda x_{p}^{j}, \lambda^{-1}u_{b}^{j}\right) \cap GR\left(V, S, \overline{u_{Eth}^{j}}\right) \neq \emptyset\right\}$$
(6)

Where λ is a scalar defining the proportionate changes and the rest is as before. We calculated the value of $ETE_g^j(x_p^j, u_b^j, \overline{u_{blh}^j})$ using MATLAB as indicated in Appendix A.

Environmental technical efficiency defined in Eq. (6) is illustrated in Fig. 2 by the distance from (x_c^j, u_{DDGS}^j) to point A which corresponds to the environmental technically efficient allocation in corn and DDGS space.

Fig. 2 - Environmental Technical Efficiency

Note however that point A does not correspond to the minimum feasible GHG level since it does not coincide with the point of tangency between the isopollution and the

graph (point B). The allocation that achieves the minimum level of GHG emissions subject to the graph is called the **overall** environmental efficient allocation.

Technically, we define this minimum feasible level of GHG emissions as:

$$\underline{GHG}^{j}\left(\overline{u_{Eth}^{j}}\right) = \min_{x_{p}, u_{b}} \left\{ GHG = \alpha_{x} x_{p} + \beta u_{b} + \gamma \overline{u_{Eth}^{j}} \quad s.t. \ (x_{p}, u_{b}) \in GR\left(V, S, \overline{u_{Eth}^{j}}\right) \right\}$$
(7)

Where $\underline{GHG}^{j}\left(\overline{u_{Eth}^{j}}\right)$ denotes minimum emissions attainable by *j* subject to observed ethanol production $\overline{u_{Eth}^{j}}$, x_{p} is the vector of pollution increasing inputs, u_{b} is the vector of byproducts and the rest is as defined before. The empirical calculation of Eq. (7) is described in Appendix B.

Overall environmental efficiency, E_g^j , is measured by the hyperbolic distance between a given observation j and the isopollution line corresponding to $\underline{GHG}^j(\overline{u_{Eth}^j})$. The hyperbolic distance is computed through calculation of the reduction of observed inputs and equiproportional expansion of observed byproducts such that the isopollution corresponding to $\underline{GHG}^j(\overline{u_{Eth}^j})$ is reached. This is illustrated by Fig. 3 where overall environmental efficiency is the distance between (x_c^j, u_{DDGS}^j) and point C.

The hyperbolic movement from (x_c^j, u_{DDGS}^j) to C results from the following technical relationship.

PROPOSITION. The measure of overall environmental efficiency, E_g^j , is related to minimum GHG in the following manner:

$$\underline{GHG}^{j} = E_{g}^{j} \alpha x_{p}^{j} + \left(E_{g}^{j}\right)^{-1} \beta b^{j} \qquad j = 1, 2, ..., J$$
(8)

See Proof in Appendix C.

Fig. 3 - Decomposition of Overall Environmental Efficiency

We can decompose E_g^j into purely technical environmental efficiency ETE_g^j (represented graphically by the distance between (x_c^j, u_{DDGS}^j) and A) and environmental allocative inefficiency EAE^j (represented graphically by the distance between A and C). Overall environmental efficiency can be expressed as:

$$E_g^j = EAE_g^j ETE_g^j \tag{9}$$

Therefore, we can define allocative environmental inefficiency residually as:⁷

$$EAE^{j} = \frac{E_{g}^{j}}{ETE_{g}^{j}} \tag{10}$$

Based on the solution to the problem described in Eq. (7) we calculate overall environmental efficiency by solving the implicit Eq. (8) for each observation. These measures of environmental efficiency and their decomposition, Eq. (10), are calculated

⁷ Environmental allocative inefficiency was illustrated in Fig. 2 by the distance between the iso-pollution corresponding to combination A and iso-pollution corresponding to point D.

for our sample of surveyed dry grind ethanol plants and reported in Table 3. The minimum feasible GHG for each DMU as defined by Eq. (7) is calculated fixing ethanol production at observed levels.

Profits and Environmental Targets: Trade off or Complementarity?

From Eq. (2) there is a clear relationship between GHG and the combination of inputs and byproducts. But there is also a relationship between combinations of inputs and byproducts and the level of profits. Therefore, in general, a change in GHG levels through reallocation of inputs and byproducts would bring about a change in profits. For a given level of ethanol production, the shadow price of GHG mitigation is the change in profits per unit change in GHG levels. The change in profits denotes the plant's maximum willingness to pay (WTP) for a permit to emit GHG. We define the shadow price of a ton of GHG as:

$$SV_{GHG}^{j} = \frac{WTP}{GHG_{1}^{j} - GHG_{0}^{j}} = \frac{\pi_{1}^{j} - \pi_{0}^{j}}{GHG_{1}^{j} - GHG_{0}^{j}}$$
(11)

Where *WTP* is willingness to pay for changing emissions from GHG_0^j to GHG_1^j . GHG_0^j denotes the original level of GHG and π_0^j the corresponding level of profits. GHG_1^j is the "targeted" level of GHG and π_1^j denotes profits at this targeted level. GHG level will be targeted at the previously defined minimum GHG (i.e. $GHG_1^j = \underline{GHG}^j$), or alternatively at the level corresponding to maximum achievable profits by firm j, π_*^j , which we designate as GHG_*^j .

Shadow Cost from Observed to Profit Maximizing Allocation

We define the profit maximizing combination of inputs and byproducts (subject to a given level of ethanol production to make it comparable with the GHG minimizing combination) as the allocation that solves the following problem:

$$\pi_*^j\left(r^j, p^j, r_{Eth}^j, GR\left(V, S, \overline{u_{Eth}^j}\right)\right) = \max_{x, u_b} \left\{ r_{Eth}^j \overline{u_{Eth}^j} + r^j u_b - p^j x \right\} \quad s.t.(u_b, x) \in GR\left(V, S, \overline{u_{Eth}^j}\right)$$
(12)

Where r_{bih}^{j} is the observed price of ethanol obtained by observation j, $\overline{u_{bih}^{j}}$ is the observed level of ethanol production by j, u_{b} is the 2x1 column vector of variable outputs (DDGS and MWDGS), r^{j} represents the 1x2 vector of observed prices of variable outputs (byproducts)⁸ obtained by observation j, x is the 1x7 vector of variable inputs (corn, natural gas, electricity, labor, denaturant, chemicals, and "other processing costs"), and p^{j} represents the 1x7 vector of observed prices of variable inputs paid by j. Quantities of labor, denaturant, chemicals and others needed to calculate GR are obtained implicitly dividing total expenditures in these categories by their price indexes described in footnote 2. Prices for these categories in equation (12) are also those in footnote 2. We will denote the allocation that solves Eq. (12) with ethanol fixed at the observed level by $\{(x_{*}^{j}, u_{*}^{j})\}$. The level GHG_{*}^{j} is calculated by inserting these values into (2).

We define the shadow value of GHG emissions associated with moving from the observed allocation to the profit maximizing allocation as:

⁸ Three DMUs in our sample did not sell dried byproducts (they sold 100% MWDGS). Since we did not have reported DDGS prices for those three observations to calculate maximum profits we used average prices of DDGS obtained by other DMUs in the same quarter.

$$SV_{GHG}^{j} = \frac{\pi_{*}^{j} - \pi^{j}}{GHG_{*}^{j} - GHG^{j}}$$
(13)

An alternative shadow cost to Eq. (13) is that which is incurred by moving from the observed to the GHG minimizing combination of inputs and byproducts.

Shadow Cost from Observed to GHG Minimizing Allocation

The GHG minimizing combination is computed by solving Eq. (7) with ethanol production fixed at observed levels and minimum GHG denoted by \underline{GHG}^{j} . Profit associated with this allocation (calculated by multiplying the GHG minimizing inputs and outputs times their respective prices) is designated as $\underline{\pi}^{j}$.

We define the shadow value of GHG related to a change from the observed to the GHG minimizing point as:

$$SV_{GHG}^{j} = \frac{\underline{\pi^{j}} - \pi^{j}}{\underline{GHG}^{j} - GHG^{j}}$$
(14)

Finally we consider the shadow value of GHG related to a change from the GHG minimizing to the profit maximizing point.

Shadow Cost from GHG Minimizing to Profit Maximizing Allocation

Such a change is illustrated in Fig. 4 in the corn and DDGS space. In Fig. 4 the GHG minimizing combination is represented by point B (the isopollution line is denoted by \underline{GHG}^{j}). If relative prices are those corresponding to the slope of π_{*}^{j} then profit maximization is achieved at point A and this requires a decrease in corn and DDGS with

respect to the GHG minimizing point. Profits at A are denoted by π_*^j and profits at B are $\underline{\pi}^j < \pi_*^j$. Emissions at B are denoted by \underline{GHG}^j and emissions at A are $\underline{GHG}^j > \underline{GHG}^j$.

Fig. 4 - Shadow Cost from GHG Minimizing to Profit Maximizing Allocation

The shadow value associated with a change from the GHG minimizing combination to the profit maximizing one is defined by:

$$SV_{GHG}^{j} = \frac{\pi_{*}^{j} - \underline{\pi}^{j}}{GHG_{*}^{j} - \underline{GHG}^{j}}$$
(15)

Results and Discussion

Environmental Performance of Ethanol Plants

Fixing ethanol production at observed levels, measures of environmental efficiency and their decomposition are calculated for our sample of surveyed dry grind ethanol plants and reported in Table 3. Results reveal that DMUs are very efficient from a technical point of view and that most environmental inefficiency comes from allocative sources. Therefore DMUs seem to have room for GHG reductions mainly by changing input and output combinations subject to the graph. In particular, the average DMU may be able to reduce emissions by 6% which amounts to 3,116 tons of CO2 equivalent GHGs per quarter (or 0.46 pounds per gallon of ethanol produced). It is of interest to know what reallocations of inputs and may actually achieve this improvement and we will go back to this point in detail later.

Profits and Environmental Targets

Shadow costs associated with moving from observed to profit maximizing allocations are reported in Table 4. Given the rather large variability across observations both the median and the average are reported as measures of central tendency. Table 4 displays some observations that are unusually high and others unusually low. These disproportionate deviations from the average are due to changes in inputs that affect profits but do not affect emissions. These inputs are labor, denaturant, chemicals, and other processing costs. We classify as "outlier" any observation whose value exceeds the average by more than 3 times the standard deviation.

An important conclusion we can extract from Table 4 is the fact that almost all DMUs reduce GHG emissions by moving from observed to maximum profits. This suggests that, under our convexity assumptions, most DMUs (including the average DMU) may be able to increase profits and reduce GHG *simultaneously* which would in turn imply that these DMUs face no trade off between economic and environmental goals at current combinations of inputs and byproducts. The fact that DMUs can rearrange inputs and

byproducts in such a way that they can both increase profits and reduce emissions prompts the following questions:

1. What inputs are reduced or increased and which byproduct is reduced or increased in such a rearrangement?

2. Why are plants not exploiting these reallocations that achieve greater profits?

The answer to the first question for the average plant is provided in Table 5. The average DMU would achieve greater profits and lower GHG simultaneously mainly by reducing the use of corn, natural gas, and electricity per gallon of ethanol produced, reducing the production of MWDGS, and increasing production of DDGS. A part of these reductions is achieved through elimination of inefficiencies that would take the DMUs to the technological frontier but for the most part they are achieved through rearrangements along the surface described by the boundary of the graph defined in Eq. (3)

The answer to the second question is not as straightforward. As noted in the discussion of the first question our DMUs may be able to increase profits and reduce GHG mainly by reducing corn, natural gas, and electricity per gallon of ethanol produced and per ton of DDGS produced.⁹ The apparent engineering (in)ability to maximize ethanol and DDGS yields when compared to other DMUs in the sample seems to drive the difference between observed production plans and profit maximizing plans for many DMUs. A note of caution is in place here. These results are based on the assumption that all DMUs are constrained by the same technological frontier. Under the assumption of homogeneous technology any difference in performance is attributed to efficiency

⁹ Reductions in MWDGS may come as a surprise. However given relative prices it appears as if this was a convenient reallocation for many DMUs.

differences rather than to technological differences. However technological heterogeneities may be present and prevent some DMUs from achieving the performance of others in the sample.

Shadow costs associated with moving from observed to GHG minimizing allocations, Eq. (14), for each DMU, average, and median are reported in Table 6. Nine DMUs lose profits while reducing GHGs, thus facing positive shadow values of GHGs, meaning a cost. Seventeen DMUs increase profits while reallocating to the minimum GHG level. The fact that the average willingness to pay for a change in allocation ($\pi_E^j - \pi^j$) is positive while average change in GHG is negative, results in negative average shadow values. Table 6 indicates that the average DMU may be able to increase profits while reducing GHG which again seems to suggest complementarity between goals. In particular the average DMU may be able to increase profits by about \$39 per ton of GHG reduced. The seventeen firms with negative shadow prices would presumably be willing to sell permits at any small price, since there is no profit lost from reducing their own GHGs.

Since there seems to be a great deal of variability in shadow prices of GHG across DMUs we have plotted a histogram that shows the approximate distribution of these values in Fig. 5. The histogram does not take into account those observations deemed as outliers. The presence of outliers is mainly due, as discussed above, to changes in inputs affecting profits but not GHG, i.e. labor, denaturant, chemicals, and other processing costs. We have superimposed to the histogram a normal density function that smoothes out the distribution. Despite the variability across DMUs, the highest frequency of shadow values (i.e. most of the "mass" of the distribution) appears to be located around

zero. This means that plants are approximately efficient in the sense that they are operating at levels for which the marginal value of GHG is around zero which is, in turn, the current GHG price that DMUs face.

Figure 5: Histogram of Shadow Values (observed to GHG-minimizing)

According to Table 7 the average DMU achieves minimization of GHG through substantial reductions in DDGS and MWDGS which in turn allows it to significantly reduce natural gas and electricity. Finally reductions in corn per gallon of ethanol are also involved in this GHG minimization. Such reallocations not only achieve reductions in GHG but also increase profits (negative shadow value)

Shadow costs associated with moving from GHG minimizing to profit maximizing allocations, Eq. (15), for each DMU, average and median are reported in Table 8. All

DMUs increase both profits and GHGs in moving from low GHG solution to high profit solution. The average DMU would forfeit \$1,726 in profit for each ton of GHG reduced, a very high cost of regulation if that firm were required to reduce GHGs. If DMUs are forced to reduce GHG emissions below profit maximizing levels, these shadow values indicate that they would be willing to purchase permits if the market value is in the vicinity of \$20 to \$30 per ton, rather than reduce one ton of GHG emissions. The histogram (with superimposed normal density) corresponding to Table 8 is plotted in Fig. 6. This histogram as the one in Fig. 5 does not take into account those observations classified as outliers.

Fig. 6 – Histogram of Shadow Values (GHG Minimizing to Profit Maximizing)

The reallocation of inputs and byproducts that would take the average DMU from the GHG minimizing to the profit maximizing combination is displayed in Table 9. The average DMU achieves increases in profits mainly through substantial increases in

DDGS which in turn entails increases in natural gas and electricity, and reductions in MWDGS. Another very important component of profit increases is reductions of corn per gallon of ethanol produced.

Results for the average DMU in Tables 4, 6, and 8 can be combined to recover the shape of the relationship between GHG and profits. Plotting the three averages in the GHG and Profit space yields Fig. 7. We denote the observed combination of the average by (GHG^{j}, π^{j}) , the profit maximizing combination by (GHG^{i}, π^{i}) , and the GHG minimizing combination by $(\underline{GHG}^{j}, \pi^{j})$. There seems to be room for simultaneous improvement of environmental and economic performance, as previously indicated in discussions of Tables 4 and 6. However, if the average firm were able to adjust inputs and byproducts to the profit maximizing combination, it would face an intense trade off described just above.

Fig. 7 - Profits and GHG

Conclusions

The purpose of this study was to contribute to the ongoing debate regarding the merits and potential of the ethanol industry in the US by investigating the current environmental performance at the individual plant level, the potential for improvement in this performance and its effects on the industry's overall emissions of greenhouse gases.

Several important conclusions can be drawn from this study. First, our results suggest that decision making units (DMUs) may have some room for improving environmental performance. However since plants are technically very efficient, most of this improvement has to come from changes in combinations of inputs and byproducts along the frontier (reduction in environmental allocative inefficiencies). By eliminating allocative inefficiencies the average DMU could apparently decrease emissions by 6%, which amounts to about 3,116 tons of CO2 equivalent GHG.

Negative shadow values of GHG from observed to profit maximizing combinations reveal that at current operating levels DMUs may be able to increase profits and reduce GHG *simultaneously*. This result points towards the existence of a synergy between environmental and economic goals rather than a trade off. Therefore plants may increase their economic viability and, in addition, help their case for public support. However if DMUs were forced to reduce GHG beyond that point our results suggest that they may face significant profit losses. In this case the average DMU in this sample would be willing to pay up to \$1,726 for a permit to emit ton of GHG, rather than suffer the profit reduction revealed by the shadow price of reducing carbon from profit maximizing to GHG minimizing levels.

The measurement of corn ethanol plants environmental performance, their potential for improvement, and profit/emissions trade offs conducted in this study should inform the debate on whether there is a place for corn ethanol as a "clean" substitute for gasoline.

Average Change (%)	-2.75	2.82	0.94	12.45	-97.65

Appendix A

The measure in (6) can be mathematically implemented through the following nonlinear programming problem:

(A.1)
$$\begin{array}{l} \underset{\lambda,z}{\operatorname{Min}} \lambda\\ s.t. \quad \lambda^{-1} u_b^{\,j} \leq M_b z, \ \overline{u_{Eth}^{\,j}} = z M_{Eth}, \ \lambda x^{\,j} \geq N z, \ \sum_j z^{\,j} = 1 \end{array}$$

Where u_b^j is the vector of dried and wet byproducts, M_b is the 2xJ matrix of observed levels of byproducts, z is the Jx1 vector of intensity variables used to weight observations and construct the piecewise linear boundary of the graph, x^j is the column vector composed by observed values of all inputs used by observation j, N is the 7xJ matrix of observed values of inputs for all observations, and $\overline{u_{Eth}^j}$ is the observed level of ethanol production of the *j*th DMU.

After multiplying the constraints times λ it is easily seen that this is equivalent to the following problem:

(A.2)
$$\begin{array}{l}
\underset{\Gamma,z'}{\underset{\beta,z'}{\text{Min }\Gamma}} \\
\text{s.t. } u_b^j \leq M_b z', \ \Gamma x^j \geq N z', \ \sum_j z^{j'} = \lambda, \ \lambda \ \overline{u_{Eth}^j} = M_{Eth} z', \ \Gamma = \lambda^2, \ z' = \lambda z
\end{array}$$

Following Färe et al. problem (1) is reformulated into problem (2) because the only nonlinear constraint is an equality constraint (i.e. $\Gamma = \lambda^2$) and is, hence, easier to program. In particular, these sub vector hyperbolic measures of technical efficiency are calculated through a nonlinear program implemented with the FMINCON procedure in MATLAB.

Appendix B

The following program describes the problem:

$$\begin{array}{l} \underset{x,u_{DDGS},u_{MWDGS}}{Min} GHG = 0.00668274 \ x_{c} + 0.063015823 \ x_{NG} + 0.0007445 \ x_{elect} \\ (B.1) & - \ 0.4197522186 \ u_{DDGS} - 0.407868 \ u_{MWDGS} \\ s.t. \ u_{DDGS} \leq M_{DDGS} z, \ u_{MWDGS} \leq M_{MWDGS} z, \ \overline{u_{Eth}^{j}} = M_{Eth} z, \ x \geq Nz, \ \sum_{j} z^{j} = 1 \end{array}$$

Where u_{DDGS} is the vector of dried byproducts, M_{DDGS} is the 2xJ matrix of observed levels of DDGS, z is JX1 vector of intensity variables, u_{MWDGS} is the vector of modified wet byproducts, M_{MWDGS} is the 2xJ matrix of observed levels of MWDGS, x is the vector of all inputs, and N is the 7xJ matrix of observed levels of inputs. This program was calculated using the LINPROG routine in MATLAB.

Based on this quantity, we calculate overall environmental efficiency by solving for E_g^j implicitly through Eq. (8) for each observation.

Appendix C

Proof:

Let us denote the vector of coefficients of Eq. (1) by (α_x, β) , where α_x is the vector of coefficients for corn, natural gas, and electricity, and β is the vector of coefficients for both byproducts. In addition, let us define an arbitrary output and input vector by (x_p, u_b) where $x_p = (x_c, x_{NG}, x_{elect})$ and $u_b = (u_{MWDGS}, u_{DDGS})$ and denote the *j*th DMU's observed output and input vector by (x_p^{j}, u_b^{j}) .

Let
$$(x_p, u_b) \in GHG_g^j (E_g^j x_p^j, u_b^j (E_g^j)^{-1}) \cap GR$$
, then $(x_p, u_b) \in GR$ and since E_g^j is a

minimum:

$$\left(\alpha_x x_p + \beta u_b\right) = E_g^j \left(0.00668274\right) x_c^j + E_g^j \left(0.063015823\right) x_{NG}^j + E_g^j \left(0.0007445\right) x_{elect}^j - \left(0.407868\right) u_{MWDGS}^j / E_g^j - \left(0.4197522186\right) u_{DDGS}^j / E_g^j$$

Let us denote observations *j* 's minimum feasible GHG level by \underline{GHG}^{j} . There are three cases to consider:

- 1. Assume $(\alpha_x x_p + \beta u_b) < \underline{GHG}^j$, then $(x_p, u_b) \notin GR$
- 2. Asume $\left\{ \left(\alpha_x x_p + \beta u_b \right) > \underline{GHG}^j \right\}$, then

$$\left\{ (v,w): (\alpha_x v + \beta w) \le \underline{GHG}^j \right\} \subseteq \left\{ (v,w): (\alpha_x v + \beta w) \le (\alpha_x x_p + \beta u_b) \right\} \text{ and since the}$$

hyperplanes defining the two sets are parallel, E_g^j can not be a minimum.

Cases 1 and 2 leave the following case:

3.
$$(\alpha_x x_p + \beta u_b) = \underline{GHG}^j$$
. Therefore $(E_g^j \alpha_x x_p^j + E_g^{j-1} \beta u_b^j) = \underline{GHG}^j$.
